Both bottom-lit and edge-lit types backlight, putting an ESR at the bottom of backlight module is necessary to reflect backlight. While the light is coupled from a light guide, a diffuser can scatter and make the light more uniform. However, the light spreads out and is wasted. To overcome this issue, a BEF, attached to the front surface of a backlight unit, is added to collect the light. Only light with a small incident angle can pass through to LC panel; light with a large incident angle will be totally reflected (total internal reflection) to ESR and redirect back to the BEF. Therefore, the uniform scattering light from a diffuser is collected by the BEF.

The non-polarized light is absorbed about 50% to become polarized light by a polarizer in the bottom-glass. To prevent this 50% waste, a DBEF can be utilized behind the bottom-glass. The DBEF can select the proportion of light which polarization direction is parallel to the polarizer on the bottom-glass (i.e., P1 in Fig. 4) and bounce the perpendicular proportion light without being absorbed and depolarized by the diffusion and scattering. (P2 in Fig. 4). This P2 polarized light becomes P1 after re-bouncing by the ESR and passes through the bottom polarizer. Using the BEF and DBEF can increase the brightness, reduce power usage or length the battery usage.

Quantum-Dot (QD) Film

In addition to the brightness enhancement films, a QD film is proposed to increase color saturation. In general, quantum dots are tiny particles, only several nanometers in size. If the material is made into the scale of the quantum dots, the electrons are easily excited to change the energy level, and then combine with the holes and finally emit light. The wavelength of light emitting energy is proportional to the size of quantum dots. Larger quantum dots emit longer wavelengths resulting in emission

Fig. 4 Optical components of a backlight module from 3M Vikuiti™. When the light coupled from a light guide in an edge-lit backlight module, the optical components are utilized to increase light efficiency and uniformity.

colors such as orange or red. Smaller quantum dots emit shorter wavelengths resulting in colors like green or blue. Therefore, we can manipulate the quantum dot size to stimulate the red, green or blue light. Quantum-dot film (Luo *et al.*, 2014) is utilized to increase image color saturation by narrowing the spectral linewidths of red, green, and blue lights, as shown in Fig. 5. By modulating the size of CdSe, CdS, and CdTe molecules in nano-meter scale, the light spectra are narrowed, thus enlarging the color gamut of an LCD.

Periphery Component

TFT Driver Integrated Circuit

Basic functions of a driver IC (Pappas *et al.*, 2009) are used to drive TFT (gate driver) and supply the corresponding voltage to LCs (data driver). The main circuit structure of the LCD is shown in Fig. 6, including (a) gate driver IC to control TFTs on and off, (b) data driver IC to supply the corresponding voltage to LCs, (c) pulse width modulation to control backlight brightness, (d) DC

Fig. 5 Quantum-dot (QD) films are utilized in a W-LED backlight system. QD-backlight can reach a wider color gamut compared with W-LED backlight. Data are from 2016 HIS.

Fig. 6 Driving structure of an LCD, including (a) gate driver IC to switch TFTs on and off, (b) data driver IC to supply the corresponding voltage to LCs, (c) pulse width modulation to control backlight brightness, (d) DC transformer circuit to provide the LCD with the required voltage, (e) gamma reference circuit to correct gamma effect, and (f) timing controller (T-Con) to control the sync signals in horizontal and vertical, and data transmission timing signal. transformer circuit to provide the LCD with the required voltage, (e) gamma reference circuit to correct gamma effect because the human eye's sense of light intensity is nonlinear with a gamma 2.2–2.5, and (f) timing controller (T-Con) is used to control the horizontal sync signals and vertical sync signals, and data transmission timing signal.

The TFT driving method can be divided into two kinds of architectures: (1) Passive matrix driving method (PMLCD): A pixel is arranged at the cross of an X- and Y- electrodes, as shown in Fig. 7. The Y-direction electrode is scanned time sequentially, and the

brightness of a pixel is determined by the difference in driving voltage between the X-electrode and the Y-electrode. The disadvantage of a passive matrix LCD is that each pixel has a relatively refreshing rate. Therefore, it is generally applied to a lower resolution display, such as a wearable device.

(2) Active matrix driving method (AMLCD): It usually has two components at each pixel: a switch TFT to control on and off and a capacitor to store the voltage, as shown in Fig. 8. The data driving circuit sends a signal to each pixel, and a gate driver controls the TFT to open or close. When a pixel of the TFT is turned on, then the pixel immediately have a voltage applied to charge the storage capacitor (Cs); when the TFT of a pixel is turned off, then this pixel has no applied voltage, and the LC can maintain its status by the voltage provided by its storage capacitor. This method provides higher response time (refreshing rate) than a PMLCD. Therefore, it is usually used in the high-level products, such as TVs or smartphones.

Trends of LC Displays

Although LCDs are still dominating to industrial, medical, and consumer electronics markets, the AMOLED is occupying the market of small-sized displays, especially in smartphones and AR/VR applications. To make LCDs continue to dominate in these markets, LCDs need to have features of a thinner, lighter, curvable, and flexible profile, lower power consumption/higher efficiency. The display industries also have to enhance LCD performances, such as brighter luminance, higher refreshing rate, higher image resolutions, and a larger color gamut. Therefore, the materials of thinner glasses, fast response LCs, higher TFT mobility and transparency, higher efficiency and color saturation of light sources are worth studying. After having a breakthrough in materials, scientists can implement existing technologies, such as local dimming and field sequential color techniques, on a new product to satisfy the consumers. The display industries also can propose advanced functions to make LCDs more useful, such as dynamically controlling refreshing rate to different operation scenarios. In a touch scenario, the refreshing rate is high to reduce the touching latency and make it more practical; in a reading mode, almost showing a static image, the refreshing rate can be adapted to lower frequency and reduce power consumption, thus lengthening the battery life. Integrating all efforts, the mature manufacturing process of LCDs still provides high quality and cost-effective to produce. Even though AMOLEDs have unique properties, but with featuring these advantages for varieties of display products, LCDs are still promising to hold the share of display markets not only in large-sized but also in small-sized display applications.

Projection Displays – LCD/MEMS/LCoS Based

Fleming Chuang, Coretronic Corporation, Taiwan, Republic of China

© 2018 Elsevier Ltd. All rights reserved.

Projection Display

A projection display system also called digital projector, projects an enlarged image on a screen. Projectors are commonly used in presentations, especially for the large size display, say, more than 100" diagonal. As shown in Fig. 1, a basic projection display includes light source which supplies the light, illumination optics which delivers the light and transforms the light beam into rectangular shape and homogenizes light onto microdisplay, and projection optics to project the image of the illuminated microdisplay and enlarge onto the screen.

The illumination optics might comprises the lens array or light pipe (or rod) and several mirrors, relay lens depends on the type of illumination method is used. In some cases, polarization of the light prior to image generation may be required for LC related microdisplay, say LCD and LCoS.

Light Source

The majority of today's projectors use HID lamp (High-intensity discharge lamps (HID lamps) are a type of electrical gas-discharge lamp which produces light by means of an electric arc between tungsten electrodes housed inside a translucent or transparent fused quartz or fused alumina arc tube) as the most common types of projector light source. In the past few years, the light source of projector move from the traditional projector lamp to solid state light source, such as LED and lasers. These new projector light sources are more efficient, environmentally-friendly and longer lasting than their predecessors.

The HID uses combination of rare earth metal salts and mercury vapor to deliver light.

The critical improvement of light lamp is to minimize the Arc gap of the lamp and increase the power to deliver more light in such a small Arc gap. As the smaller the Arc gap is, as higher the light collection efficiency of illumination optics can be.

Used in smaller projectors (so called, pico-projector or pocket-projector), LEDs are essentially applied. LED light sources are mercury-free and can power off and on instantly. The output lumens for the top line LED projectors are targeting for 3K lumens. The life time of LED projectors can last up to 20,000 h at least. It reaches its maximum brightness in several seconds and requires no cooling down period as shut-down it. In comparison old mercury lamps requires several minutes to boost-up to maximum brightness and it can be damaged if unplugged before the cooling down period ends.

In addition to the light source itself, it normally comprises the light collection optics and prisms as well as optical component needed for homogenization, and in some cases, polarization of the light prior to image generation. The imager module is the active component that generates the image from the incoming light.

In early 2010, Sony announced the development of a highly-efficient RGB laser light source with 10,000 h life-span. Since then, Laser projector became the primary developing direction for projection players. Also respectable is the lasers' considerably higher brightness, better contrast and wider color gamut compared to traditional projector lamp.

Microdisplay

Currently there are three types of microdisplay that are widely used in projection display, namely digital mirror devices (DMDs), transmissive liquid crystal displays (LCDs) panels and liquid crystal on silicon (LCOS). The Microdisplay is a key part of the system since most of the optical limitations are influenced by its properties (dimensions, polarization, acceptance angle, etc.), hence those will affect its design structures.

Fig. 1 Basic structure of a projection display.

Projection display – LCD

In 1989, Epson announced the first LCD projector. This projector was developed using three HTPS LCD (HTPS is an abbreviation of High Temperature Poly-Silicon, an active matrix transmissive LCD) panels. The classical structure of 3-LCD projector is shown in Fig. 3 which uses UHP lamp as a light source. The lamp projects white light onto a combination of mirrors that split the light into its three basic video colors. The three color images are combined using a cross dichroic prism (x-prism) (Robinson *et al.*, 2005a) (Cross dichroic prism (X-prism) is combination of 4 triangular prisms. It has function of combining R, G and B three color beams to form the color image) to form a full-color image consisting of millions of colors. The image passes through a projection lens and is projected onto a screen.

The LCD panel applied in projection is HTPS LCD. It has a thin-film transistor (TFT) generated by poly-silicon in each pixel. These pixel transistors act as a conduction switch by changing the scan line's voltage. They are produced in the same way as semiconductors. They are small and highly reliable because they can easily be miniaturized (pixilation or high open area ratio) and drivers can be generated on substrates by processing at a high temperature (Fig. 2).

HTPS LCD panel only transmits longitudinal waves of light. The most popular and effective polarization converter system is a strip half-wave plate. Polarization converter is equipped behind the second lens array (Lens B in Fig. 3). The lens array plate, comprising an array of lenslet, is used to divide light source of individual lenslet into small portion. By passing these focused second light sources through the half-wave plate (Fig. 4), the unified polarization state is formed and the divided light source is superimposed on to the LCD panel by condenser lens and field lens.

Below the projection lens (in Fig. 3), the Cross Dichroic Prism is combination of four triangular prisms. It has function of combining R, G, and B three color beams from respective LCD panels to form the color image. The R/G/B panel should be well aligned and lateral color of projection lens is also required with well control to achieve the crispy pixel imaging.

The 3-LCD projector has three panels to serve for R/G/B separately. Therefore, it does not have possible artifact problems-rainbow effect (Brennesholtz *et al.*, 2008) (The rainbow effect is a visual artifact possible on many single-chip DLP projectors. Because there is only one image chip, color is created sequentially with a rotating color wheel. The sequential color action of slower color wheels can be seen by some people). That principally exists in DLP projector if the frame fresh rate is not high enough. The distinguished advantage of LCD over DLP is the light collection efficiency. LCD can deliver higher lumen output ratio (amount of lamp brightness) in same level color performance and power consumption.

Fig. 2 First HTPS LCD panel using inorganic alignment layer. Available at: <https://phys.org/news/2005-02-world-https-lcd-panel-inorganic.html>.

Fig. 3 Structure of LCD projector and Polarization converter (see “Relevant Websites” section).

Fig. 4 Stripe Half-Wave-Plate.

Fig. 5 Typical LCoS structure.

It is known as the screen door effect and resulted in such a sharp image that it was possible to see the individual pixels. With today's advanced resolution and micro-lens equipped in front of LCD panel, the pixels are so small that it becomes harder to notice the screen door effect even though it still exists.

An LCD projector uses three panels that light passes through to yield the full-colored image. Because of this, it is possible for any panel to fall out of alignment which will cause one of the three stacked images to be shifted slightly; this is called convergence. If it happens, then the on-screen image will be slightly fuzzy.

Projection Display – LCoS

Liquid crystal on silicon (LCoS or LCOS) is a miniaturized reflective active-matrix liquid-crystal microdisplay using a liquid crystal layer on top of a silicon backplane. LCoS was initially developed for projection display, but it is also used for wavelength selective switching, structured illumination, near-eye displays and optical pulse shaping, etc. By way of comparison, HTPS LCD projectors are using transmissive LCD, allowing light to pass through the liquid crystal; however, LCoS is reflective LCD. A typical LCoS structure is shown in [Fig. 5](#).

In an LCoS panel, a CMOS chip controls the voltage on square reflective aluminum electrodes buried just below the chip surface, each controlling one pixel with an independently addressable voltage. Typical LC cells are about 1–3 micrometers thick and pixel pitch range from sub-ten microns, as small as $2.79\ \mu\text{m}$ (see “Relevant Websites” section). A common voltage for all the pixels is supplied by a transparent conductive layer made of indium tin oxide (ITO) on the cover glass. The pixels are generally coated with a reflective aluminum layer, and a polyimide alignment layer. The liquid crystal industry can take advantage of the existing silicon technology to produce high resolution microdisplays that is easy and inexpensive to fabricate.

In LCOS, liquid crystals are applied to a reflective mirror substrate. The input light is always modulated into longitudinal polarization light (*s*-wave). The PBS (Robinson *et al.*, 2005a) (Polarizing Beam splitters (PBS) are used to split unpolarized light into two polarized parts. PBS is Beam splitters designed to split light by polarization state) is the most common light switching optical element to control the light in or out. (Fig. 6).

There are methods to increase the contrast of LCoS and LCD projection system. If a PBS is used as the exit analyzer, the isolating QWP (Quarter-wave plate (QWP) consists of a carefully adjusted thickness of a birefringent material such that the light associated with the larger index of refraction is retarded by 90° in phase (a quarter wavelength) with respect to that associated with the smaller index) can work with a retarder stack filter to enhance the ANSI contrast (Robinson *et al.*, 2005a). By applying the Wire grid polarizer into system, it could increase the NA and keeping high contrast at the same time (Brennesholtz and Stupp, 2008; Robinson *et al.*, 2005b).

There are a few typical optical architectures which have been using in the three-panel LCoS projection system. In the system, each panel separately modulates red, green, and blue light. such as, Philips color prism (US Patent 6,330,113), three PBS plus x-prism (Armitage *et al.*, 2006a), three wire-grid polarizer plus x-prism (Armitage *et al.*, 2006b), three PBS plus three lenses (US Patent 7,198,373), off Axis Illumination (Bone, 2001) and ColorQuad (US Patent 6,183,091), etc. You may see the details in the respective references for above diversified architectures. The most popular type is three PBS plus x-prism, shown in Fig. 7. They used dichroic mirrors to separate the three colors, each of which is directed to the corresponding LCoS panel with a separate PBS.

Skew rays are corrected by QWPs between the PBS and the panel. The reflected images are combined into a full color image in an x-prism prior to the projection lens. This design is conceptually simple and allows the optimization of each color channel separately.

Fig. 6 On and off for PBS and LCoS.

Fig. 7 3-PBS/x-prism LCoS projection system.

Projection Display – MEMS

The DMD™ chip is a micro-electro-mechanical systems (MEMS) array of fast digital micromirrors, monolithically integrated onto and controlled by an underlying silicon memory chip (Hutchison, 2007). (Left of Fig. 8).

The operation principal of DLP projector is shown in Fig. 8 (right). Grayscale patterns are created by programming on/off duty cycle of each mirror, and multiple light sources can be multiplexed to create full RGB color images. Each mirror represents one pixel. The light, rather than passing through the panel, is reflected from it. The mirrors move back and forth, varying the amount of light that reaches the projection lens from each pixel of the primary colors in a rapid rotating sequence to for the true color image.

Optical systems for DLP could be divided into single-panel and three-panel projection applications. (Fig. 9).

Optical systems for single-panel projection applications can be grouped into two main architectures, Telecentric and Non-Telecentric system. Telecentric architectures are defined by locating the exit pupil of the illumination system (entrance pupil of the projection lens) at or near infinity from the device surface. The chief rays of every bundle incident on every mirror then are essentially parallel to each other. For the illumination system, this provides uniform angles of incidence across the entire field, creating uniform black levels for the dark field. Non-Telecentric architectures differ from Telecentric in that the exit pupil of the illumination path is located a short, finite distance from the device, and the entrance pupil of the projection lens must be coincident with it. Some designs use a field lens (or lenses) instead of a prism directly in front of the device to perform the angle separation. The field lens must be on axis with the remainder of the projection lenses, but is shared by the illumination path. This presents some challenges in illumination design since these field lenses also are part of the illumination path, but are off-axis to the DMD and tilted to the illumination path. By designing the illumination pupil near the stop of the projection lens and folding the illumination path there, a very compact system can be designed.

Fig. 8 Structure of DMD chip and simplified optical function. (Courtesy: Texas Instruments Inc.).

Fig. 9 Generic Optical System: single panel and 3 panels. (Courtesy: Texas Instruments Inc. (Im, H., Kim, W., Chung, J., 2010. A new transmissive type tilting actuator for a smooth projected television image. Proceedings IMechE 224 Part C: J. Mechanical Engineering Science 1327–1333.)).

A three-chip DLP projector uses a prism to split light from the light source, and each primary color of light is then routed to its own DLP chip, then recombined and routed out through the lens. It completely eliminates the “Rainbow” effect of single-chip DLP. 3-Chip DLP Projectors are used for high-performance, high brightness applications in large rooms and large audience venues. 3-Chip DLP technology is currently considered the top of the line technology for digital projection (Im *et al.*, 2010).

New Technologies, Challenges, and Applications in Projection Display Industry

There are many important improvements of the projection display undergoing, no matter what kind of microdisplay is applied. For example, color by applying new solid state light source (LED or Laser), product to meet new HDR standardization, component to improve the dynamic range, image resolution enhancement, UST lens, etc.

4K × 2K: True 4K and 4k by Smooth Picture

As the most advanced digital projection technology for cinema, with 4k digital cinema solutions deployed, DLP and LCoS have their own products. Both are based on 3-chip solutions. By utilizing three 1.4" 4K DMD chips, the manufactures could deliver the Cinema projector's brightness as high as 20K lumens. JVC and Sony have revealed its new native 4K HDR projector, which features a newly-developed laser light source with a claimed brightness of 3000 lumens. However, the price of true 4K 3 LCoS projector is very high no matter DLP or LCoS.

A pixel shifting technique which focuses on producing a smooth picture on the lower resolution panel, DLP and LCoS have their own approaches. So called e-shift by JVC, the operation principle is explained how they work (in Fig. 10). In this diagram at the left-corner of figure, the refractive index of the e-Shift device is changed through use of an electric image shift-switching signal. Following, the path of light emitted by the light sources (such as the D-ILA display device) changes, following the changed refractive index. By changing the path, one pixel is shifted diagonally (vertically and horizontally). By shifting pixels, the vertical and horizontal resolution is substantially doubled. It shows “quadruple” the amount of effective pixels, but it cannot be addressed that small portion of the pixel to display unique information. It has to be the entire pixel and when you put together the two sub frames the entire pixel from the non-shifted and shifted image have to be color coordinated to look like the original image.

JVC has 4K e-shift D-ILA front projector by three full HD resolution D-ILA devices. For the DLP camp, so called “Smooth Picture” technique is developed for the similar pixel shift purpose as well (Hutchison, 2007). For example, the transmissive type of Smooth picture module is operated by vibration to tilt the light from the DMD of optical system (equipped between projection lens and DMD). A voice coil motor (VCM) type actuator for smooth picture has to satisfy performance requirements such as higher driving force, lower power consumption, and lower cost. In updated development (Im *et al.*, 2010), TI developed the 0.67" 2.5K × 1.6K DMD for single chip projector. By applying smooth picture module, the high quality 4K picture is achieved. Several companies have introduced the 4K DLP projectors into market.

The e-shift device would also be available for reflective type (Hutchison and Neal, 2008) instead of transmissive type mentioned above. Compared to transmissive type, it requires a very good quality mirror and more precisely tilt angle control.

Fig. 10 Pixel shift-switching using the e-Shift device.

Ultra-Short-Throw

The terminology, Throw Ratio, refers to the ratio of the distance to the screen (throw) to the screen width (Fig. 11). A larger throw ratio corresponds to longer distance of a projector from the screen. For an Ultra-Short-Throw (UST), it is very short distance the image is thrown onto the screen, and it has a large effect on screen size. Often in home projector and individuals lacking the space in the room, projector to equip with an ultra-short-throw projection lens is quite popular in the market. As the throw ratio is as below as 0.35, we could call it UST. The critical issue for the projection lens design is that it requires a very large field of view; therefore, design and manufacturing become challenging.

Some special design techniques were developed in UST projector. In popular lens structure of projection system, the stop is positioned to make the system Telecentric or non-Telecentric to match the light beam of illumination system. It is always located close to focal point of the rear part (the lens elements at right of stop) of projection lens. Generally, multiple glass and plastic lenses are combined and large-diameter lenses are used to achieve the target performance. Thus, the wider the viewing angles, the larger the lenses and the more the number of the lenses. The requirements to widen the viewing angles of a projector are inversely proportional to reducing the projector's size and weight causing the manufacturing difficulties, especially; the aspherical surface is mostly applied for reducing the aberrations of lens system.

Some optical structures applied the reflecting mirror at most front position of projection lens was developed. There are two types of mirror: convex mirror and concave mirror. To reduce the size of lens element, forming the intermediate stop or intermediate image between the mirror and front lens element is also designed by many developers. Some distinguished design examples from the published patent are described below.

US Patent 7,009,765 (Fig. 12): One intermediate image and one intermediate stop to reduce the size of front lens group. No mirror is applied.

US Patent 20130162957 (Fig. 13): No intermediate image or stop applied, using convex mirror. The mirror and first lens will be large.

Fig. 11 Definition of Throw Ratio.

Fig. 12 US Patent 7,009,765B2, Assignee: Infocus.

Fig. 13 US Patent 20130162957 A1, Assignee: Young Optics.

Fig. 14 US Patent 7441908, Assignee: Ricoh.

US Patent 7441908 (**Fig. 14**): One intermediate image is formed in front of concave free-form mirror.

US Patent 9,372,388 (**Fig. 15**): two intermediate image, one intermediate stop, and using concave mirror. This structure has the most compact reflection mirror and lens element.

Laser Phosphor Illumination Projector

Pure laser, also known as RGB laser, generates light directly from three individual red, green and blue lasers. The primary benefit of a RGB laser system is light output while also achieving higher performance in other standard image quality parameters such as color gamut, contrast ratio and dynamic range when compared to standard lamp-based systems. As such, RGB laser is ideal for largescale applications and giant screen cinema.

Laser phosphor illumination projector (**Fig. 16**) uses blue laser diodes as the light source instead of a high intensity discharge lamp to generate the three primary colors in a single DMD laser phosphor projector, the blue laser diode focuses laser light onto a phosphor wheel (Laser phosphor is a lampless projection illumination platform that uses blue laser diodes as the primary light source. To generate the three primary colors – red, blue, green – the blue light from the laser diodes shines onto a spinning wheel that is coated in a phosphor compound) to create red and green light, while blue laser light passes through an opening in the phosphor wheel. These red, green, and blue colors are then directed onto SLM chip, which directs the light through a lens and onto the projection screen. The basic concept is shown as **Fig. 16**. In a laser-phosphor light source, only uses the less expensive blue lasers, that can be made more cost-effective compared to pure laser projectors.

Fig. 15 US Patent 9,372,388 B2, Assignee: Nittoh K.K.

Fig. 16 Laser-phosphor projector (a single-chip projector) (Barco).

The primary advantage of a laser phosphor projector is the long life of the illumination system. As a lampless system, laser phosphor also eliminates the need for lamp and, in many designs, filter replacements, reducing the down-time, maintenance and costs associated with lamp-based projectors.

There are diversified optical structures in designing the laser phosphor projector. The phosphor wheel could be reflecting type (Fig. 17) or combined with color filter to make structure compact, like below patent application (Fig. 18).

Color Gamut and HDR

Displays cannot reproduce all the colors occurring in nature. HDR content preserves details in the darkest and brightest areas of a picture that are lost using current standards. It also allows for more natural, true-to-life colors that are closer to how we see them in real world. High Dynamic Range display provides viewers with an enhanced visual experience by providing images that have been produced to look correct on brighter display, that provide much brighter highlights, and provide improved detail in dark areas. Extension of the color gamut, necessary to realize more realistic color reproduction, is possible achieved by changing the chromaticity of the three primary colors. DCI-P3 describes a wider color gamut than Rec. 709 with three primary colors and is implemented for digital cinema based on xenon arc discharge lamps. Rec. 2020 reproduces images more realistically and includes the gamut of the major colorimetric standards but requires quasi-monochromatic light sources such as RGB lasers. The chromaticity diagram (CIE 1931) of Rec. 709, DCI-P3, and Rec. 2020 are shown in Fig. 19. The HDR regulation for HDR10

(see “Relevant Websites” section) and Dolby Vision (see “Relevant Websites” section) could be found in reference. Solid state light sources are gradually becoming the preferred light sources for projection displays instead of the traditional (broadband) short-arc xenon or ultra-high performance (UHP) discharge lamps.

Fig. 19 Standard Color Gamut. Plotted on a CIE 1976 Uniform Chromaticity Diagram.

Fig. 20 US Patent 7224335 Assignee: IMAX DMD-based image display systems.

Dynamic irises (Laser phosphor is a lampless projection illumination platform that uses blue laser diodes as the primary light source. To generate the three primary colors – red, blue, green – the blue light from the laser diodes shines onto a spinning wheel that is coated in a phosphor compound) first came into general use with LCD projectors as a means for improving on this projector's relatively low native on/off contrast ratio and elevated black levels. Dynamic irises can now be found in many home theater projectors using DLP, LCoS and 3LCD digital display technologies including those with a relatively good native contrast ratio and low black levels.

When SLM based projection systems are to be used to meet the HDR regulation, it is desirable that the system has a high spatial resolution and that the system possesses a wide dynamic range image quality. SLM based systems such as those based on DMDs are typically limited to contrast ranges of 1000: 1 or less. IMAX proposed invention dual SLM structure is directed towards a projection image display systems that employ so-called reflective spatial light modulators (SLMs) such as those in the form of digital micro-mirror devices (DMDs). It relates to techniques for using multiple SLM devices arranged serially. The invented system (**Fig. 20**) comprises a controller, a first reflective SLM and a second reflective SLM. The first reflective SLM is operatively coupled to the controller to receive first image data from the controller and is aligned to receive light from a light source and to reflect imaging light correlated to the first image the second reflective SLM is operatively coupled to the controller to receive second image data from the controller and is aligned to receive imaging light from the first reflective SLM and to reflect modified imaging light.

Assume DMD has 100% optical efficiency and supports n bit depth, if the first DMD maintains 2^k equally spaced brightness levels, a serial DMD device should have a dynamic range performance equivalent to $k + n$ bit depth, at least within the lowest level (US Patent 7224335). Hence, by applying dual-DMD, the contrast ratio could meet the HDR regulation by well design.

3D Displays, Stereoscopic/Autostereoscopic 3D

Yi-Pai Huang and Chun-Ho Chen, National Chiao Tung University, Hsinchu, Taiwan

© 2018 Elsevier Ltd. All rights reserved.

Introduction of 3D Display

In recent years, the requirement is emerging for more vivid and realistic 3D experience. The development of 3D display technology comes from the desire of human's nature vision, and results from the maturity of manufactory and display technology. The public usually record and display images for memorizing and sharing activities with others. Therefore, display is the closest electronics product to human. The progress of display development represents the efforts of pursuing more realistic visual experience. When we review the display developing history, human's color perception ability is a strong driving force to replace black-and-white TVs with full color ones. More than one trillion vision cells also encourage us to replace standard definition displays with full high definition ones. In addition to the progress of color and definition, a depth perception is a disruptive innovation of display technology. 3D displays utilize this depth perception to demonstrate the real 3D world (Holliman, 2005). Watching the primary 3D displays needs to wear eye glasses, which is called the stereoscopic type (Hill and Jacobs, 2006). The glasses usually block human's line of sight and do not be assimilated into our life. The scenarios could be limited in movie theaters (Srivastava *et al.*, 2010). Therefore, the glasses-free technology, or called the auto-stereoscopic type, obtains more attention to be applied on billboards, TVs, and mobile phones.

Principle

Our world is a three-dimension space but there is only two-dimension intensity distribution in our retina. However, the human's vision system can transfer this planar intensity distribution to the stereo concept by multi depth cues. Depth cues are classified by psychological and physiological depth cues (Pastoor and Wopking, 1997).

Psychological Depth Cue

Even the objects in the same distance, viewers perceive the closer objects when the objects are more colorful and brighter. Besides, human considers the relative small object is far than the big object in the same image. This is due to the perspective cue as shown in Fig. 1(a). The spacing of two parallel lines seems to decrease when the distance of lines away from the viewer increases. The stereo perception also comes from the variation of light and shadow as shown in Fig. 1(b). In addition, the occlusion cue between objects help determining near and far objects. The near object blocks the viewing of far objects as shown in Fig. 1(c). Moreover, the texture gradient in near objects contains more detail and surface feature on objects infer 3D shape and distance as shown in Fig. 1(d).

Physiological Depth Cue

The crystalline lens in the eye structure, exactly as the focus lens in the camera, can accommodate itself to image the object on the retina. And the viewing lines of two eyes converge on the object. Based on the different depth, this converging angle varies. Near objects have wide converging angles and far objects have narrow converging angles. The average distance between two eyes is 6.5 cm. This distance induces a little difference between the viewing angles of two eyes. Therefore, the image disparity of object on

Fig. 1 Illustration of psychological depth cues such as (a) linear perspective: parallel lines converge at distance point on horizon, (b) shading: cast by an object gives a strong depth cue, (c) occlusion: invisible portion of objects behind an opaque object, and (d) texture: surface feature on objects infer 3D shape and distance.

Fig. 2 (a) Binocular and (b) motion parallax provide the image disparity that our brain can merge to create 3D perception.

two retinas exists, called binocular parallax as shown in [Fig. 2\(a\)](#). According to this parallax, human can perceive the difference of object depth. Furthermore, when the viewer's eye moves, the image disparity of object also varies, called motion parallax as shown in [Fig. 2\(b\)](#). 3D displays apply the depth cues of parallax to realize stereo images. If the viewer wants to perceive a clear 3D image, two eyes can only receive individual images with the disparity.

Health Issue– Visual Fatigue

3D techniques use 2D left/right images and depth cue to yield 3D illusion in our brain. In the physiology, how the left/right images are received by the left/right eyes not only affects the 3D effectiveness but also the comfort level in the psychology. For examples, the interference between left and right image can degrade the 3D perception and may induce the visual fatigue ([Pastoor and Wopking, 1997](#)). One issue of 3D display is the accommodation–convergence conflict (A.C. conflict). While the human eye's convergence capability perceives the correct depth of 3D objects, the accommodation function makes the eyes focus on the display screen as shown in [Fig. 3\(b\)](#). Since there is a close interaction between convergence and accommodation, this A.C. conflict often causes visual fatigue in 3D viewers ([Pastoor and Wopking, 1997](#)). The relation between accumulated fatigue and eye disease is worth further exploring in the future. The 3D display revolution is still waiting for more research on physiological and psychological fields.

Stereoscopic and Auto-Stereoscopic Display

From the 19th to 20th century, 3D displays mainly belong to the stereoscopic type in need of special eye glasses. The glasses and other technical issues limit the popularization of 3D displays. By the end of the 20th century, more and more efforts have been made on the auto-stereoscopic display. These 3D displays are introduced as follows.

Polarizing Glass

The pixels of display are divided into odd rows and even rows. Micro-retarder film, arranged with corresponding rows, polarizes light into orthogonal polarization states ([Wu et al., 2008](#)). The viewer wears the glasses with polarization films for individual states. The binocular parallax can be achieved because another polarization will be blocked. The image interference could happen when view's head rotates with the linear polarization. Circular polarization is preferred to avoid this interference ([Jung et al., 2009](#)). The major issue is resolution decreasing, only a half of 2D images.

Fig. 3 In (a) real world, convergence and focal distance (accommodation) is the same; however, accommodation–convergence conflict (A.C. conflict) would happen on (b) 3D display. Reproduced from Hoffman, D.M., Girshick, A.R., Akeley, K., Banks, M.S., 2008. Vergence–accommodation conflicts hinder visual performance and cause visual fatigue. *Journal of Vision* 8, 33. doi: 10.1167/8.3.33

Anaglyph

Anaglyph is also called red-green glasses as shown in Fig. 4. Complementary colors for individual eyes are presented in one image. When viewer wears the red-green glasses, the glasses can filter out another color light. The binocular parallax can be achieved. In anaglyph 3D, partial color is filtered out by color glasses, resulting in poor color performance. Anaglyph 3D has also the resolution issue compared to 2D images.

Shutter Glasses

The display alternatively plays right and left images with a double frame rate. The viewer wears the glasses with liquid crystal shutters, which is synchronized by the display. The shutter switches on and off sequentially and each eye can receive its corresponding image. Because of vision persistence, these left and right image sequences are fused together in our brain, achieving the stereo perception. This technology can overcome the resolution decreasing issue, but the drawback is higher cost than other passive glasses. The battery is also needed for the active glasses.

Head Mounted Display

This kind of 3D display provides left and right two displays just in front of our eyes. The head mounted display can solve the interference between left and right images due to independent display for each eye (Tomilin, 1999). Only one viewer can watch 3D at once. Usually, the device is expensive, heavy, and uncomfortable for long-time wearing (Keller *et al.*, 2008).

These stereoscopic displays effectively yield a pair of disparity images to produce our stereo perception. However, viewers must wear eyeglasses when they watch the stereoscopic display. Therefore, the auto-stereoscopic display, which is eyeglasses-free, was developed.

E-Holography

This auto-stereoscopic display consists of red/green/blue lasers as light sources and acoustic optical modulator (AOM) as a phase grating (Javidi and Tajahuerce, 2000). Through the vertical scanning mirror and polygonal mirror, the lasers scan in vertical and horizontal direction to form a phase hologram (Son *et al.*, 2010). The 3D image size is limited by the AOM size and the scan speed of polygonal mirror must be synchronized with lasers (Takaki and Okada, 2010). This system will meet great challenge in data processing and mirror scan speed if the system scales up (Takaki *et al.*, 2010).

Volumetric

This volumetric display is composed by the spiral surface and bottom laser light source (Soltan *et al.*, 1995). When the light is projected to the rotated spiral surface, the light is scattered as a point of image. The spiral surface will scan all points in the working space to form the whole image as shown in Fig. 4. This kind of 3D display presents a transparent image without depth cue of occlusion (Refai, 2009). Meanwhile, in the region close to rotating axial, the slower speed induces a partial blurring image (Gately *et al.*, 2011). These effects degrade the stereo perception.

Fig. 4 3D displays classification based on with or without eyeglasses is divided into two groups, stereoscopic and auto-stereoscopic including various kinds of technologies (Jung *et al.*, 2009; Tomilin, 1999; Keller *et al.*, 2008; Javidi and Tajahuerce, 2000; Son *et al.*, 2010; Takaki and Okada, 2010; Takaki *et al.*, 2010, 2011; Soltan *et al.*, 1995; Refai, 2009; Gately *et al.*, 2011; Suyama *et al.*, 2004; Kuribayashi *et al.*, 2006; Hsu *et al.*, 2008; Berkel and Clarke, 1997; Young and Javidi, 2005; Chen *et al.*, 2009; Maphepo *et al.*, 2010; Tsuboi *et al.*, 2010; Takaki, 2010; Holliman *et al.*, 2011; Nakamura *et al.*, 2012; Hamagishi, 2009; Im *et al.*, 2008; Javidi and Okano, 2002; Son and Javidi, 2005; Sato, 1979; Woodgate, 2003, 2005; Willemsen and De Zwart, 2006; Krijn and de Zwart, 2008; Li and Wu, 2011; Ren and Wu, 2004; Naumov *et al.*, 1998; Ye and Sato, 2010; Chang *et al.*, 2014; Uehara *et al.*, 2013).

Multi-Planar

Two LCD panels are used in this multi-planar 3D display (Suyama *et al.*, 2004). These two LCD panels present the front and back image individually. The depth cues of various light and shadow in different viewing distance are applied to integrate front and back images. Precise alignment between the front and back panel could be a manufacturing issue (Kuribayashi *et al.*, 2006). In addition, only in the direct view direction, viewers can obtain the stereo perception. For other oblique viewing angle, the mismatch of two images cannot provide a 3D concept (Hsu *et al.*, 2008).

Time-Multiplexed

The LCD makers commonly apply the multiplexed type for 3D displays. One panel provides at least two views in time or spatial domain (Berkel and Clarke, 1997; Young and Javidi, 2005). In the time-multiplexed type, the left and right images are sequentially sent to left and right eye. Different from eyeglasses of stereoscopic display, the light guiding devices are implemented inside the LCD panel (Holliman *et al.*, 2011). When the switching speed is higher than that of our brain can distinguish,

the fusion of stereo images occurs. This 3D display preserves the resolution but requires a high frame rate LCD panel (Hamagishi, 2009).

Spatial-Multiplexed

Lenticular lens is attached on the LCD panel for guiding light from odd/even column pixels to left/right eyes (Im *et al.*, 2008). The cylindrical lens can focus and refract light from one image into more than two sub-images (Chen *et al.*, 2009; Takaki, 2010). The number of sub-images determines the number of views in stereo perception. More views can provide more continuous 3D viewing concept when viewers are moving their heads. In addition, parallax barrier is also popular as a light splitting device for disparity images (Maphepo *et al.*, 2010). The barrier is a black and transparent strip lines to restrict the light path from LCD panel to eyes. One eye of viewers only receives light from a specific LCD region (e.g., the odd or even column pixels); the other one eye receives light from the other region. Compared to the lenticular lens, the light intensity of barrier 3D display is lower due to the barrier's blocking light (Tsuboi *et al.*, 2010).

Integral Imaging Display

An integral imaging display uses the micro-lens array instead of the cylindrical lenses used by lenticular lens display (Javidi and Okano, 2002). Each micro lens directs light from the pixels and covers in different horizontal and vertical directions, thus producing a full parallax image. Therefore, the floating 3D image can be achieved by integral photography theory (Son and Javidi, 2005). The integral imaging display has an issue of image overlapping in oblique viewing angles. By modifying the pixel emitting into correct micro lens, this issue can be overcome (Javidi and Okano, 2002).

LC Lens for a 2D/3D Switchable Display

Spatial-multiplexed display degrades the image resolution, even just presents 2D contents. The advantage of LC lens-based switchable display is to preserve the high image resolution in 2D display mode (Sato, 1979). By switch-on the LC lens, display will show the 3D images (Ren and Wu, 2004; Naumov *et al.*, 1998; Ye and Sato, 2010). Three types of LC lens, polarization active micro-lens (Li and Wu, 2011), active LC lenticular lens (Krijn and de Zwart, 2008), and electric-field-driven (Willemsen and De Zwart, 2006), had been reported and successfully demonstrated. LC alignment direction (LCAD) (Woodgate, 2005) and electrode array direction (EAD) (Woodgate, 2003) was then proposed to have 3D rotational function for mobile display (Chang *et al.*, 2014; Uehara *et al.*, 2013). Additionally, the temporal scanning LC-lens (Huang and Chen, 2012), such as multi-electrode driven (MeD) Fresnel LC lens was proposed to improve the resolution of 3D images (Huang *et al.*, 2010).

Super-Multi-View Display

Due to the limitation of the number of multi-view, there is always discontinuity of view switching with respect to the viewing direction. This effect degrades the 3D perception. Super-multi-view (SMV) techniques use an extremely large number of views (e.g., 256 or 512 views) to generate more natural 3D display visual effects (Takaki *et al.*, 2011). The horizontal interval between views is smaller than the diameter of the human pupil. Light from slightly different viewpoints enters the pupil simultaneously. This is called the SMV display condition (Nakamura *et al.*, 2012). SMV provides smooth motion parallax and reduces the A.C. conflict since the brain unconsciously predicts the image change due to motion.

Augmented and Virtual Reality Display

Although wearing a head mounted display (HMD) is not very convenient for users, but Augmented Reality (AR) and Virtual Reality (VR) technologies can produce the virtual images to make people's brain perceived as a real 3D object. In addition, the hardware devices have been improved to be much lighter than that in the 20th century. AR/VR HMD becomes a popular system for many applications. The major difference between AR and VR is that VR make people thoroughly immersed with an ocular head mounted device, interactivity with sensory feedback. While AR only produces the virtual images covering part of observer's field of view and integrate the images with the environmental background.

There are several optical arrangements to render the images for AR and VR applications. For an occlusion type, mainly for VR application, the display can be placed closed to the eyes, then use optical lens to generate a virtual image with large field of view, as shown in Fig. 5(a). While in the case of see-through type, mainly for AR applications, the optical setup includes off-axis and partially reflective mode, light guided mode, or total internal reflection mode, to combine the virtual image with environmental scenes, as shown in Fig. 5(b).

The applications of AR/VR displays are not only limited on consumer electronics, such as video games, video entertainment, or live events. This technology can be further used on healthcare/medical, engineering, education, retail, and military field. Such as in the case of medical application, the VR display combined with a brain-wave detector can be used for detecting glaucoma damage

Fig. 5 Optical structure of (a) virtual reality head mounted display. The lens is placed in front of the eye and micro display located near eye is floated to the desired depth. (b) Augment reality head mounted display. The micro display is located at the side part of the observer and the displayed virtual information is bent to the eye by the optical combiner.

(Chien *et al.*, 2013; Lin *et al.*, 2015). It could even potentially allow users to routinely and continuously monitor the electrical brain activity associated with visual field in their living environments, representing a transformative way of diagnosing and monitoring disease progression in not only glaucoma but other functional visual losses.

Spectacle-Type

Spectacle-type of wearable display, also known as head mounted display (HMD), includes two major categories, augmented reality (AR) HMD and virtual reality (VR) HMD. Both AR and VR technologies produce the virtual images for human eyes and make people's brain perceived as something really exists. The major difference between AR and VR is that VR make people thoroughly immersed with ocular device, while AR only produce the virtual images covering part of observer's field of view and integrate the images with the environmental facilities.

There are several optical arrangements to render the images for AR and VR applications. For occlusion type, mainly for VR application, the display can be placed very closed to the eyes, or use mirror to direct the light into the human pupil to render images, and maximize the field of view (FOV), as shown in Fig. 1(a).

While in the case of see-through type, mainly for AR applications, the optical setup includes off-axis and partially reflective mode, light guided mode, and TIR mode, to maximize the observation of environmental scene, which thus decreased the FOV, as shown in Fig. 1(b). For different application segments, the optical designs may differ. For example, in the smart glasses application which can function like handless cellphone, the aesthetic appearance is more essential, while in the case of medical application, the resolution and contrast become much more important. As shown in Fig. 2(a) and (b), it is very helpful for a doctor to use

Fig. 1 The optical setup of AR and VR includes two basic arrangements: (a) totally occlusion with near-eye display and (b) optical combiner with light-guiding system. fluorescent image to identify the ordinary cell and the tumor cell. In this application, the doctor can conveniently observe by wearing the smart glasses.

Clothes-Integratable-Type

With the upcoming trend of "internet of things, IoT," people expect every device can be integrated with clothes or environments, which can make the users can "hands off." To realize this fantasy, the devices need to be flexible and stretchable, and so do the displays. Making display flexible is of one route, while making it stretchable is the other. Here, we introduce essential technologies for achieving flexible and stretchable displays, and therefore, these technologies can be combined for realizing clothes integrated type of wearable display, as shown in Fig. 3 (Lee *et al.*, 2016).

Flexible Displays Integrating With Clothes

Some wearable displays integrated with clothes were demonstrated, which are expected to provide more functions for users beyond the current smart phone applications. However, the appearance is still not aesthetic enough for fashion design, because the existing technology cannot be stretchable and conformable for fashion designers to realize their design (Fig. 4).

Flexible Displays Integrating With Human Body

Along with the development of flexible electronics, more and more sensors were prepared that contributes to human's convenience. For the further application, the integration with human body makes these devices more attractive.

Therefore, sensors are expected to be attached to the human body and people will need to know what the sensors detected. For example, the detected temperature sends the signal of your body condition that is needed to be known timely and a human-sensor interaction is therefore essential for practicability. In this regard, as an information carrier, a wearable display was also needed in these applications. The integration with human body makes this kind of flexible display different from the conventional. There are several design considerations should be included. Because the direct contact with human skin, the attached devices should not affect human's health as well as the ability of other activities. On one hand, the flexibility should be fully realized that does not

Fig. 3 (a) Photographs of freestanding stretchable 4-digit 7-segment on coin (upper) and skin (lower). (b–d) Photographs of operation of stretchable all-ink-jet-printed 4-digit 7-segment display with initial and stretched state (b), when attached to skin (c) and crumpled (d). obstruct human's activities. To satisfy this requirements, our display should be flexible and stretchable to adapt muscle movement. So an integration with several rigid substrates cannot be accepted. On the other hand, the materials of good biological compatibility and breathability should be chosen as the flexible substrates. And the complex operating environment of human body raise new demands of endurance. Taking these considerations into account, the wearable display can not only succeed the advantages of light weight and facile fabrication of flexible devices and also be applied on human body that makes human's life more convenient.

Watch-Type

Display makers tried very hard to make the watch-type of display looks like conventional, especially the appearance needs to be round. The pixel array used in display is usually in rectangular arrangement. By applying special algorithm to dim the lightness a bit around the boundary, it is possible to render round watch appearance with conventional rectangular pixel arrangement (**Fig. 5 (a)**). In addition, by folding the COF underneath the watch, the form factor can be as slim as the actual watch.

Flexible Substrates

Flexible displays are made with flexible components including substrates, thin film transistors (TFTs), and display medium. Usually, the devices need to be annealed to stabilize and optimize the performances. However, flexible for ordinary TFT device processing. Polyethylene naphthalate (PEN) has better thermal durability, however, ordinary TFT needs 350°C of post-annealing, it is still too low in this case. Polyimide (PI) can endure 350°C and its thermal expansion coefficient matches with substrate made of plastics are not endurable for high temperature processing, while flexible substrate made of steel are too heavy to be made for mobile devices. As shown in **Table 1**, polyethylene terephthalate (PET) is the cheapest one, however, its glass transition temperature (T_g) is too low for other layers of a flexible device, however the cost of PI is still too high for consumer products. As a result, scientists are paying much attention develop a substrate with simultaneously high T_g , high transparency (for aesthetic purpose), high flexibility, and low cost.

Flexible TFT

Flexible TFT is also a critical component of flexible display, taking charge of controlling the grey scale of each pixel. The desired features of a good flexible TFT array are high switching speed, low power consumption, high aperture ratio, good flexibility, and reliable electrical performances. The material characteristics for these requirements are high mobility of semiconducting layer, low resistance of connection metal line, small capacitance coupling between layers, smaller area of TFT blocking the transmissive light, high power efficiency by eliminating the unwanted polarizers or color filters, capability of active layers to be deformed, and the stable material characteristics after photo or electrical stressing.

Here is the summary of flexible TFTs, as shown in **Table 2**. Organic TFT has the best capability of being bent, however, its mobility is still too low for high end applications, such as smart phone. Amorphous Si TFT (*a*-TFT) is the most mature TFT, well adopted in existing displays, however, its flexibility is not good enough for future wearable displays. While oxide TFT seems to have better overall performances in terms of flexibility, mobility, cost, and compatibility with existing manufacturing facilities. However, the oxide TFT still needs to be improved for its long-operation reliability, which is induced by the stressing and resulting the electrical performance degradation.

Table 1 Basic properties of film used for base substrates

	PET	PEN	PC	PES	PAR	PCO	PI
CTE (−55 to 85°C) ppm/°C	1.5	13	60–70	54	53	74	17
Transmission at 400–700 nm (%)	>85	>85	>90	90	90	91.6	yellow
Water absorption	0.14	0.14	0.2–0.4	1.4	0.4	0.03	1.8
Young's modulus (GPa)	5.3	6.1	1.7	2.2	2.9	1.9	2.5
Tensile strength (MPa)	22.5	275	NA	83	100	50	231

To accommodate the exiting processes for flexible TFT array, the plastic substrate is usually bonded onto the rigid substrate with releasable adhesive. As shown in Fig. 6(a), the TFTs were formed onto a pre-laminated substrate with the structure of plastic/adhesive/carrier-plate by conventional photo-lithography, and be peeled off after the TFT array finished. Other modified approaches include using sacrificing layer as shown in Fig. 6(b) and using transfer process as shown in Fig. 6(c). They are all based on the concept of adopting existing TFT process, while forming the TFT arrays on the flexible substrates, as shown in Fig. 7.

Table 2 The comparison of flexible TFTs

		Poly-Si	Amorphous-Si	Organic TFT (Pentacene)
Performance	Mobility	Very Good	OK for PHOLEDs	OK
	Leakage	OK	Very good	OK
	Stability	Good	Issue	Issue
	Uniformity	Issue	OK	Issue
Manufacturability		Maturing	Excellent	N/A
Cost		> Medium	Medium	Low??
Plastic-substrate compatibility		Under development	OK	Excellent
Metal-foil-substrate compatibility		Good	Good	Good

Fig. 7 A handling process for making flexible TFT array. Reproduced from Li, Z.M., Lv, Q.M., Huang, Y.J., 2010. Versatile soft backplane Technology. Journal of Industrial Materials.

Flexible Organic Light Emitting Diode

There are two major kinds of flexible display made of organics: small molecules, and polymer materials (usually called polymer light emitting diode, PLED, to differentiate with small molecular organic light emitting diode, OLED). The former one was firstly invented by Dr. Ching W. Tang in Kodak, and the latter was invented by Prof. Richard Friend's team at University of Cambridge. The lighting mechanism of OLED is to inject both electrons and holes from cathode and anode, respectively, where both carriers would transport in the organic layers to form excitons, and later on illuminate the light and go back to the energy ground state. To optimize the lighting efficiency, the rate of injection, transportation, and recombination of electrons and holes should be delicately designed.

Flexible OLED can perform the best image quality, however, it is very vulnerable to moisture and oxygen, which thus needs to combine with flexible passivation technology before it can be commercialized (the structure is shown in Fig. 8; Ma *et al.*, 2010). The mature technology used for passivation is the multi-stacking of organics and inorganics, where inorganics are used for blocking the oxygen or water molecules's diffusion, and the organics are used for balancing the inter-layer stress while being bent. The other popular method is called atomic layer deposition (ALD), which is made with certain reactive precursors, mixing with reacting gas and precisely forming an atomic layer for passivating the OLED. As the layer is of atomic level, the device is ultimately flexible.

Flexible E-Paper

Different from the lighting mechanism of flexible OLEDs, flexible electrophoretic displays (EPD) can reflect the ambient light to show the image. Because the image appearance is similar to actual paper, it is usually called E-paper. Not only EPD, but also many other kinds of reflective display technologies are promising for future E-paper applications, such as liquid powder, electro-wetting, electro-chromic, cholesteric liquid crystal, polymer dispersed liquid crystal displays, and so on. Among them, EPD is the first flexible display commercialized for e-reader applications, however its color image performance is not as good as flexible OLED, and it is not suitable for video application because of its slow updating speed. Even though, EPD has two unique advantages superior to flexible OLED, one is the good sunlight readability due to its particle scattering, and the other is the power-saving due to its bistability.

The fabrication processes of making E-paper includes two major categories: microcapsule type and micro-cup type, and both of them can be leveraged for future flexible display fabrication. Both type of E-paper includes the synthesis of particles, formulation with surfactant and additives, encapsulated with a small chamber (either capsule or cup), and then laminated onto the flexible substrate with roll-to-roll (R2R) processes.

To realize a full-color E-paper, many approaches have been proposed. The easiest way is to add on color-filter (Lai *et al.*, 2012), however, considering the low reflective efficiency, the image was not good enough. Usually users do not like this kind of vague color image. Until recently, E-ink demonstrated a structure utilizing multiple color particles within one microcup to render color images by selectively control certain particle to be on top of the surface (Telfer and McCreary, 2016). This approach has the best performance in terms of contrast, color saturation, and resolution. However, such method needs to mix many kinds of color particle in one small chamber, and thus the fabrication repeatability is hard to control and the driving scheme is quite complicated. To overcome such difficulty, transfer method to spatially deploy the particle color particles to sub-pixels, which only need two kinds of color particles within one chamber was demonstrated, and thus the process is much easier to control and the driving scheme is comparably simple.

Flexible Liquid Crystal Display

LCD is the most mature display technology in display thus far. It would be imperative if LCD can be flexible. However, the high birefringence of the plastic substrate is an issue since LCD is polarization dependent. As shown in Fig. 9(a) (Oka *et al.*, 2016), phase retardation caused by the high birefringence is relevant to thickness of the plastic substrate. So several approaches have been

Fig. 8 A structure of thin film encapsulated OLED. Reproduced from Ma, R.Q., Rajan, K., Silvernail, J., *et al.*, 2010. Wearable 4-in. QVGA full-color-video flexible AMOLEDs for rugged applications. *Journal of the Society for Information Display* 18, 50–56.

Fig. 9 (a) Deformation of plastic substrate during bending, (b) flexible LC device with polymer wall spacers, and (c) the principle of BOA to solve the BM shift issue in curved LCD panel. Reproduced from Ishinabe, T., Obonai, Y., Fujikake, H., 2016. A foldable ultra-thin LCD using a coat-debond polyimide substrate and polymer walls. *SID Digest 47* (1), 83–86; Ye, C.L., Fu, R.H., Qiu, J., *et al.*, 2016. The application of BOA on curved panel. *SID Digest 47* (1), 25–27.

taken: phase compensation film (Pin Hsiang *et al.*, 2016), in-cell polarizer (Fujiwara *et al.*, 2016), ultrathin substrate (Oka *et al.*, 2016; Pin Hsiang *et al.*, 2016) and low birefringence plastic substrate (Ishinabe *et al.*, 2016). Besides, thermal durability of plastic substrate is also important because of the high temperature during the LCD device fabrication process. Polyimide (PI) is widely applied as thermal durable plastic substrate, whose glass transition temperature ($> 200^{\circ}\text{C}$) is compatible with LCD fabrication. However, PI needs further material design to be colorless since it is a little yellowish.

In addition to plastic substrate, curvature mismatching between different layers is another critical issue, which needs flexible spacers, black matrix alignment, etc. (as shown in Fig. 9(b)). Recently, Prof. T. Ishinabe from Tohoku University demonstrated with a so-called coat-debond method to fabricate the low birefringence polyimide (PI) and polymer wall spacer to make a flexible LCD demo, which has testified that flexible LCD is possible to be a candidate for future flexible display applications. Polymer walls used as the flexible spacer which could stick both substrate together are able to maintain the cell gap when compressing the device (Ishinabe *et al.*, 2016).

Flexible Transparent Conductive Film

The desired feature of conductors for wearable displays are: flexibility, stretchability, transparency, and conductivity. Conventional conductors like Indium Tin oxide (ITO) seem too fragile in flexible applications. Currently, the most popular substitute materials are graphene and its derivatives, metal nanowire, carbon nanotubes, and two-dimensional materials, which are all compatible with flexible substrate. However, carbon based materials synthesize still needs vacuum and even toxic process, which increases the cost. Two-dimensional materials are also challenging for large size preparation process. Metal nanowire such as silver nanowire forms conducting network. According to percolation theory, the ratio of conducting component which is non-transparent could be decreased to increase the transmittance with high conductivity, which is considered as one of the promising material.

Since metal nanowire is not transparent, it's essential to trade off the transmittance and conductivity. Several methods have been proposed including metal mesh, alignment coating, stacking structure, etc. (Yang *et al.*, 2016).

Patterning of flex transparent conducting film (Flex-TCF) is critical for device applications. The conventional way is lithography, but the etching recipe and conditions are totally different from ones in glass-based process. The plastic substrate is softer and less chemical resistive than glass, which means the Flex-TCF needs milder treatment to avoid negative effects to the substrate.

In order to be compatible with solution-based process and roll-to-roll fabrication, hydrophile/hydrophobic treatment is a more appropriate patterning method. Common hydrophile treatment includes UV/Ozone, plasma and chemical decoration. Defining the hydrophile/hydrophobic region first, then coat the dispersion of conducting material on the substrate and tends to assemble in the hydrophile region.

Practical Processes for Flexible Display

To make a mass-producible flexible device, the key processes of thin-film deposition, registration, patterning, surface treatment, and lamination should be developed. As Prof. Jun Souk analyzed, the ultimate approach is to use roll-to-roll (R2R) process (Souk and Roh, 2012) without vacuum ambience and photo-lithography. These patterning methods were mature in the newspaper or magazine printing industry.

Nonuniqueness in Imaging

Greg Gbur, University of North Carolina at Charlotte, Charlotte, NC, United States

© 2018 Elsevier Ltd. All rights reserved.

Glossary

Computed tomography Also known as computed axial tomography, a classic technique by which multiple X-ray absorption images of an object are taken and digitally reconstructed into a two- or three-dimensional image of the object's internal structure.

Condition number The ratio of the largest singular value of a matrix to its smallest. A large condition number (much greater than unity) implies that inversion techniques involving the matrix are highly susceptible to noise.

Ewald limiting sphere Sphere in Fourier space that characterizes the complete information that can be determined in a scattering experiment if data are taken for all directions of incidence and illumination.

Ewald sphere of reflection Sphere in Fourier space that characterizes the information that can be determined in a scattering experiment for a single direction of illumination.

Ill-conditioning Refers to a linear inversion problem with a high condition number, which is therefore highly unstable in the presence of noise.

Ill-posedness Refers to a linear inversion problem in which at least one of the following conditions is not satisfied: existence, uniqueness, and continuity.

Inverse problem A physical problem in which a "cause" is deduced from measurements of an "effect," in essence inverting the usual cause-effect type of problems usually studied in physics.

Inverse scattering problem Problem in which the structure of a scattering object is determined by measurements of the field scattered by the object.

Inverse source problem Problem in which the structure of a primary radiation source is determined by measurements of the radiated field. Known to be nonunique due to the existence of nonradiating sources.

Noncontinuity Refers to a linear inversion problem in which the reconstructed object is highly sensitive to even small changes in the image data.

Nonexistence Refers to a linear inversion problem in which the measured data may not correspond to any known object, due to the presence of noise.

Nonradiating source A primary radiation source which does not, in fact, produce any radiation.

Nonuniqueness Refers to a linear inversion problem in which multiple objects produce the same image.

Phase problem Imaging problem in which a source distribution is determined from measurements of the intensity of the image alone.

Prior knowledge Additional knowledge, usually dictated by the physics of an inverse problem, in order to make the solution unique.

Singular value decomposition Mathematical technique by which any matrix may be decomposed in such a way that the singular values (essentially diagonal elements of the decomposition) can be used to assess the stability of any inversion technique.

Overview

The techniques of optical imaging may be considered a subset of the broad class of so-called inverse problems, in which a general "cause" of a phenomenon is deduced from measurements of the "effect," namely, the phenomenon itself. This process of cause determination reverses the usual study of physics, in which the "effect" is deduced from knowledge of the "cause." In this context, the latter case is usually referred to as the forward problem. A familiar example of an inverse problem is computed tomography, the determination of the internal structure of a patient from measurements of the intensity of X-rays transmitted through the body. The cause is the human body itself, while the effect is the absorption of X-rays.

Because of this reversal of the familiar causal process of physics, inverse problems are often beset with difficulties. Chief among these is nonuniqueness, in which the measured data is insufficient, even in principle, to uniquely determine the properties of the object. In this article, we discuss the manifestation of nonuniqueness in a general imaging system, and the typical means by which it is overcome, if possible. Examples of nonuniqueness are given in the form of the inverse source problem and the phase retrieval problem.

Matrix Formulation of Imaging and Inverse Problems

We introduce the mathematics of nonuniqueness by considering an abstract imaging system, as illustrated in Fig. 1. We assume that the object data is characterized by the vector $|o\rangle$ and that the image data are characterized by the vector $|i\rangle$; the action of the imaging system is described by the matrix A . Assuming a linear relation between object and image, we may express the imaging process as

$$|i\rangle = A|o\rangle \quad (1)$$

Fig. 1 Illustration of the notation for a general imaging system, in which an object vector $|o\rangle$ is converted to an image vector $|i\rangle$ through the action of an imaging system characterized by a matrix A .

It is to be noted that we have drawn the geometry in [Fig. 1](#) as a traditional imaging system, in which a planar object is mapped to a planar image through the action of a “black box” imager, such as a system of lenses. However, the formalism to be used here applies to much more general systems. For example, in computed tomography, the object may represent a three-dimensional (3D) map of an object’s absorption coefficient, and the image data may represent X-ray projection data acquired through multiple measurements with different orientations of the tomographic device. In general, we are considering systems in which the total measured data of the image is $|i\rangle$, and the desired information about the object is represented by $|o\rangle$.

It is also to be noted that the physics of such an imaging problem is usually described by continuous functions and operators; that is, the object $o(\mathbf{r}')$ is mapped to an image $i(\mathbf{r})$ through an integration with an integral kernel $A(\mathbf{r}, \mathbf{r}')$ over the domain D of the object, such that

$$i(\mathbf{r}) = \int_D A(\mathbf{r}, \mathbf{r}') o(\mathbf{r}') d^2 r' \quad (2)$$

Since practical imaging problems inevitably require the discretization of such integrals, however, [Eq. \(1\)](#) is sufficient for our description.

In the presence of noise, we may modify [Eq. \(1\)](#) by adding a noise vector $|n\rangle$ to the image, with the result

$$|i\rangle = A|o\rangle + |n\rangle \quad (3)$$

It is easiest to analyze the case for which A is a square $N \times N$ matrix, but more general $M \times N$ matrices may also be considered. When $M > N$, the image data collected is less than the amount of information available about the object, and it is expected that only a limited reconstruction of the object is possible. When $M < N$, more image data are collected than are in principle useful for reconstruction.

For a square Hermitian matrix, the properties of the imaging system may be characterized by the eigenvalues and eigenvectors of the matrix. However, as an imaging matrix is not necessarily Hermitian nor square, it is more appropriate to instead represent it using the singular value decomposition (SVD), given by

$$A = \sum_{i=1}^r s_i |y_i\rangle \langle x_i| \quad (4)$$

where $r = \min(M, N)$, the vectors $|y_i\rangle$ are the eigenvectors of the Hermitian $m \times m$ matrix $Y = AA^\dagger$, the vectors $|x_i\rangle$ are the eigenvectors of the Hermitian $n \times n$ matrix $X = A^\dagger A$, and $s_i = (x_i)^{1/2}$, with x_i the eigenvalues of the matrix X (or Y , if $N < M$). The vectors $|y_i\rangle$ are orthonormal, so that $\langle y_i | y_j \rangle = \delta_{ij}$, and also $\langle x_i | x_j \rangle = \delta_{ij}$. By [Eq. \(4\)](#), it can be readily seen then that

$$A|x_i\rangle = s_i|y_i\rangle, \quad A|y_i\rangle = s_i|x_i\rangle \quad (5)$$

The singular values are taken to be nonnegative by definition, which suggests that the signs of the eigenvectors must be taken appropriately. In matrix form, the SVD may be written as

$$A = USV^\dagger \quad (6)$$

where U is an $m \times m$ unitary matrix made up of the eigenvectors $|y_i\rangle$ of Y , V is an $n \times n$ unitary matrix made up of the eigenvectors $|x_i\rangle$ of X , and S is an $m \times n$ “diagonal” matrix such that $S_{ij} = \delta_{ij}s_i$. More information about the SVD can be found in [Trefethen and Bau \(1997\)](#).

We may apply this decomposition to formally find a solution to the imaging equation ([Eq. \(1\)](#)). Assuming for the moment that all the singular values $s_i \neq 0$, a solution is given by

$$|o\rangle = V\hat{S}U^\dagger|i\rangle \quad (7)$$

where $\hat{S}$ is an $n \times m$ diagonal matrix with diagonal elements equal to $1/s_i$. The meaning of this solution is elaborated upon in the next section.

Nonuniqueness and Prior Knowledge

Let us now restrict ourselves to the ideal case in which $m=n$; the matrices $\mathbf{U}$, $\mathbf{V}$, and $\mathbf{S}$ are all square $m \times m$ matrices. The ability to solve our imaging problem then depends directly on the properties of the singular values s_i , and not on an overabundance or dearth of data.

An imaging problem is said to be well-posed if the solution exists, is unique, and is continuous. Any problem which fails to meet all of these conditions is said to be ill-posed, in a sense that was first introduced by Hadamard (1902). We next consider each of these conditions related to ill-posedness and how they are related, as well as basic strategies to ameliorate them.

The imaging system $\mathbf{A}$ may be viewed as a general mapping of the object data to the image data. The object data lies within an m -dimensional space called the object space, while the image data lies within another m -dimensional space called the image space. The set of all possible objects is referred to as the domain, while the set of all possible images is known as the range. The domain may be a subset of the object space, depending on how it is defined: for example, the object space might be considered as the set of all two variable functions, while the object domain might be defined as the set of all finite-valued two variable functions. The dimensionality of either the domain or range may be lower than that of the space in which it is embedded – or both. These regions, and the problems of nonuniqueness, noncontinuity, and nonexistence, are illustrated in Fig. 2.

Nonuniqueness is the case where two or more objects have exactly the same image. This arises when one or more of the singular values $s_i=0$. An object $|\mathbf{o}\rangle$ is said to lie in the null space of the imaging system if

$$\mathbf{A}|\mathbf{o}\rangle = 0 \quad (8)$$

Any object vector in the null space will contribute nothing to the image; therefore, if $\mathbf{o}_1$ represents an object, and $\mathbf{o}_2$ represents a null space vector, then $\mathbf{o}_1$ and $\mathbf{o}_1 + \mathbf{o}_2$ will have exactly the same image. Without additional information (to be discussed momentarily), there is no way to determine the contribution of the null space vector, or vectors, to the object. The values $s_i=0$ clearly make the inversion matrix $\hat{\mathbf{S}}$ singular, as it would contain terms of the form $1/s_i$.

As will be made explicit by example in the next section, the presence of nonuniqueness in an imaging problem may therefore be tied to the existence of invisible objects. An object which lies entirely in the null space will have no detectable image; it is invisible. Nonuniqueness in an imaging problem therefore implies the existence of invisible objects, and vice versa.

Nonexistence is closely related to nonuniqueness. The existence of null space vectors results in the range of the image having a smaller dimensionality than the domain of the object. There are, therefore, vectors in the image space that simply cannot be produced by an object. In a perfect imaging system, this would not be a problem; however, in the presence of additive noise $|\mathbf{n}\rangle$, it is possible for the image vector to be moved out of the range, in which case there exists no corresponding object.

Noncontinuity is a situation in which two very different objects produce very similar images. Strictly speaking, noncontinuity refers only to an integral imaging model, such as given by Eq. (2), in which the reconstructed object function $o(\mathbf{r})$ does not depend continuously on variations of the image function $i(\mathbf{r})$. In a discrete matrix model, the analogous problem is known as ill-conditioning, and arises when at least one of the singular values is extremely small compared to the others. To characterize this, we introduce the condition number κ , defined as the ratio of the largest singular value to the smallest,

$$\kappa \equiv \frac{s_{\max}}{s_{\min}} \quad (9)$$

A condition number which is not too much greater than unity (within two orders of magnitude) indicates a well-conditioned system, while an extremely large condition number represents ill-conditioning. Because the matrix $\hat{\mathbf{S}}$ depends on $1/s_i$, any vector corresponding to a very small singular value will be strongly amplified. In the presence of noise, this means that noise will also be highly amplified in an ill-conditioned system and will tend to drown out object information.

To resolve the issue of nonuniqueness, one must typically introduce prior knowledge based on known physics of the imaging system, as illustrated schematically in Fig. 2. Often, only a small class of mathematically achievable objects are physically reasonable, and restricting to this class will in some cases make the imaging problem unique; in other cases, additional prior knowledge may be needed. In phase retrieval problems, for instance, the size of the object is generally known and any

Fig. 2 Illustration of the different types of ill-posedness that can appear in an imaging system.

reconstruction which is much larger than this, or infinite, is rejected. Another commonly used condition used as prior knowledge is that the “physical” solution $|\mathbf{o}_t\rangle$ have minimum “energy,” i.e.,

$$\langle \mathbf{o}_t | \mathbf{o}_t \rangle \leq \langle \mathbf{o} | \mathbf{o} \rangle \text{ for any acceptable } \mathbf{o} \quad (10)$$

Prior knowledge needs to be chosen carefully based on the imaging problem being solved; it is possible to find a unique solution, which is nevertheless not useful or even closely related to the desired object.

In the context of the SVD, the best possible solution is often defined as the solution $|\hat{\mathbf{o}}\rangle$ which minimizes the quantity L , defined as

$$L \equiv |A|\hat{\mathbf{o}}\rangle - |\mathbf{i}\rangle| \quad (11)$$

It can be shown that this minimum solution is given by

$$|\mathbf{o}\rangle = V\hat{S}U^\dagger|\mathbf{i}\rangle \quad (12)$$

where $\hat{S}$ is the $n \times m$ diagonal matrix with diagonal elements equal to $1/s_i$ for $s_i \neq 0$ and 0 for $s_i = 0$; this is a generalization of Eq. (7). In essence, this solution calculates only those parts of the object that do not lie in the null space and ignores the rest. The solution can be further conditioned by setting the diagonal elements equal to zero for $s_i < S$, where S is a chosen critical value depending on practical properties of the system. In principle, throwing away those components of the solution which have small singular values results in a loss of information; however, as we have noted, those components would typically be corrupted by noise and overall be detrimental to the solution in any case.

The minimum solution of Eq. (12) in practice acts as an application of prior knowledge, though it may be said to be philosophically different. The minimum solution is unique because it simply ignores the null space of the operator A ; ideally, prior knowledge is used to deduce the part of the solution which lies in the null space.

The Inverse Source Problem

One of the simplest, and perhaps most infamous, examples of nonuniqueness in an imaging problem is found in the inverse source problem. The geometry and related notation is illustrated in Fig. 3. We consider a 3D monochromatic primary source of light, confined to a domain D , defined by the function $q(\mathbf{r})$ and which produces a monochromatic field $u(\mathbf{r})$. The field and source are related by the 3D Helmholtz equation,

$$[\nabla^2 + k^2]u(\mathbf{r}) = -4\pi q(\mathbf{r}) \quad (13)$$

where $k = \omega/c$, ω is the frequency and c is the vacuum speed of light. We consider the scalar wave equation for simplicity, but similar arguments can be applied to a full electromagnetic radiation problem.

The solution for the field everywhere inside and outside the source domain is given by

$$u(\mathbf{r}) = \int_D \frac{e^{ikR}}{R} q(\mathbf{r}') d^3 r' \quad (14)$$

with $R = |\mathbf{r} - \mathbf{r}'|$. At a distance far away from the source, we may make the far zone approximation,

$$\frac{e^{ikR}}{R} \approx \frac{e^{ikr}}{r} e^{-iks \cdot \mathbf{r}'} \quad (15)$$

where $\mathbf{r} = r\mathbf{s}$, with $\mathbf{s}$ a unit vector pointing in the direction observation. In the far zone, then, the field may be written as

$$u(r\mathbf{s}) \approx \frac{e^{ikr}}{r} \int_D q(\mathbf{r}') e^{-iks \cdot \mathbf{r}'} d^3 r' \quad (16)$$

Fig. 3 Illustration of the notation and geometry of the inverse source problem.

The integral is now in the form of a 3D spatial Fourier transform, i.e.,

$$\tilde{q}(\mathbf{K}) = \frac{1}{(2\pi)^3} \int q(\mathbf{r}') e^{-i\mathbf{K} \cdot \mathbf{r}'} d^3 r' \quad (17)$$

In terms of this Fourier transform, we may write the far zone field as

$$u(r\mathbf{s}) \approx (2\pi)^3 \frac{e^{ikr}}{r} \tilde{q}(k\mathbf{s}) \quad (18)$$

It should be clear from this expression that any information about the source is contained in the Fourier transform, which depends only on the angular direction $\mathbf{s}$.

The inverse source problem may then be posed as an imaging problem as follows: given measurements of the field $u(r\mathbf{s})$ for all directions $\mathbf{s}$, determine the 3D structure $q(\mathbf{r})$ of the source. This problem has been shown to be severely nonunique due to the theoretical existence of invisible objects, known in this context as nonradiating sources. From Eq. (18), it can be seen that a nonradiating source is one for which

$$\tilde{q}(k\mathbf{s}) = 0 \text{ for all } \mathbf{s} \quad (19)$$

An example of such a nonradiating source is not difficult to come by (Kim and Wolf, 1986). Let us imagine a spherical source of radius a and uniform charge density q_0 , such that

$$q(\mathbf{r}) = \begin{cases} q_0, & |\mathbf{r}| \leq a \\ 0, & |\mathbf{r}| > a \end{cases} \quad (20)$$

The far zone field radiated by this source can be readily shown to be of the form,

$$u(r\mathbf{s}) = 2\pi \frac{e^{ikr}}{r} j_1(ka) \quad (21)$$

where $j_1(x)$ is the spherical Bessel function of order 1. The far zone field will be identically zero, i.e., the source will be nonradiating, if ka is equal to any of the zeros of $j_1(ka)$. The first zero of this Bessel function is at $ka = 4.49$, implying that the smallest nonradiating source of this structure has a radius $a = 4.49/k$.

Though radiationless sources have a long history in physics (Gbur, 2013), the influence of such sources on the inverse source problem was not clear until the 1980s, when a heated scientific argument clarified the matter (see Devaney and Sherman (1982) and the comments which follow).

It may be readily seen that the inverse source problem is what we might call fatally nonunique: the information present in the radiated field provides almost no information about the object structure. This can be seen by introducing a new nonradiating condition equivalent to Eq. (19). We multiply Eq. (16) by $\exp[i\mathbf{k} \cdot \mathbf{r}]$, and then integrate overall values of the unit vector $\mathbf{s}$; the result is a necessary and sufficient condition for a source to be nonradiating, of the form

$$\int_D q(\mathbf{r}') j_0(k|\mathbf{r} - \mathbf{r}'|) d^3 r' = 0 \text{ for all } \mathbf{r} \quad (22)$$

The spherical Bessel function $j_0(k|\mathbf{r} - \mathbf{r}'|)$ has a well-known modal expansion, namely,

$$j_0(k|\mathbf{r} - \mathbf{r}'|) = 4\pi \sum_{n=0}^{\infty} \sum_{m=-n}^n j_n(kr) j_n(kr') Y_n^{m*}(\theta, \phi) Y_n^m(\theta', \phi') \quad (23)$$

where $Y_n^m(\theta, \phi)$ are the spherical harmonics.

Let us now consider a general spherical source $q(\mathbf{r})$ of radius a . Integrated over such a spherical domain, the spherical harmonics are orthogonal. The condition given by Eq. (22) is therefore equivalent to the requirement that the nonradiating source $q(\mathbf{r}')$ be orthogonal to the infinite set of modes given by $j_n(kr') Y_n^m(\theta', \phi')$. However, for a fixed value of n and m , i.e., a fixed angular dependence, it is clear that there are an infinite number of orthogonal modes with the same angular dependence but different radial dependence (see examples given in Gbur and Wolf (1997)). It may be loosely stated that, for each mode that produces a measurable radiation pattern, there are an infinite number of modes with the same angular dependence that do not radiate.

Because of the fatal nonuniqueness of the inverse source problem, it is not generally possible to deduce anything significant about the source structure from the radiation pattern. The problem can be made unique by assuming (Porter and Devaney, 1982) that the source has minimum energy E , i.e., by minimizing the functional

$$E = \int_D |q(\mathbf{r}')|^2 d^3 r' \quad (24)$$

but this condition gives the same result as the SVD problem of Eq. (11), in that all the nonradiating source components are identically zero. This minimum energy condition does not seem to hold in realistic radiation problems.

Often, though not always, the uniqueness or nonuniqueness of an imaging problem can be determined by a simple dimensional analysis. From Eq. (18), it is to be noted that a measurement of the complete radiation pattern of a 3D source $q(\mathbf{r})$ determines the Fourier components $\tilde{q}(k\mathbf{s})$ on a spherical shell in 3D Fourier space. Because the function $\tilde{q}(\mathbf{K})$ is the Fourier transform of a function of finite extent, it follows that it is the boundary value of an analytic function in three complex variables,

Fig. 4 Illustration of the notation and geometry of the inverse scattering problem.

K_x , K_y , and K_z . However, such a function can only be analytically continued if information is known in a 3D volume of space: the information on the two-dimensional (2D) shell is not sufficient to analytically continue the existing Fourier data to a volume.

Nonuniqueness can sometimes be the result of an insufficiently diverse dataset. This can be illustrated by the inverse scattering problem under weak scattering conditions, as illustrated in [Fig. 4](#). An incident field $u_i(\mathbf{r})$ impinges on a localized scattering object of refractive index $n(\mathbf{r})$, producing a scattered field $u_s(\mathbf{r})$. The total field $u(\mathbf{r}) = u_i(\mathbf{r}) + u_s(\mathbf{r})$, and the incident field is defined as the field that would exist in the complete absence of the scatterer.

The total field satisfies the Helmholtz equation with inhomogeneous wave number,

$$[\nabla^2 + n^2(\mathbf{r})k^2]u(\mathbf{r}) = 0 \quad (25)$$

As is shown in [Born and Wolf \(1999, Chapter 13\)](#), this equation can be written in the form

$$[\nabla^2 + k^2]u_s(\mathbf{r}) = -4\pi F(\mathbf{r})u(\mathbf{r}) \quad (26)$$

where $F(\mathbf{r})$ is the scattering potential, given by

$$F(\mathbf{r}) = \frac{k^2}{4\pi} [n^2(\mathbf{r}) - 1] \quad (27)$$

[Eq. \(26\)](#) is formally the same as [Eq. \(13\)](#) for the source problem, and the far zone solution may be found in the same way to be

$$u_s(r\mathbf{s}) \approx \frac{e^{ikr}}{r} \int_D F(\mathbf{r}') u(\mathbf{r}') e^{-ik\mathbf{s} \cdot \mathbf{r}'} d^3r' \quad (28)$$

The difficulty with this solution is that the scattered field appears on both sides of the equation, implicitly in $u(\mathbf{r})$, making [Eq. \(28\)](#) an integral equation that cannot in general be solved. If one assumes that the scattered field is extremely weak, however, then $u(\mathbf{r}') \approx u_i(\mathbf{r}')$, and we have

$$u_s(r\mathbf{s}) \approx \frac{e^{ikr}}{r} \int_D F(\mathbf{r}') u_i(\mathbf{r}') e^{-ik\mathbf{s} \cdot \mathbf{r}'} d^3r' \quad (29)$$

Let us now further assume that the incident field is a plane wave propagating in a direction specified by the unit vector $\mathbf{s}_0$, of the form $u_i(\mathbf{r}) = \exp[ik\mathbf{s}_0 \cdot \mathbf{r}]$. Then the scattered field is of the form,

$$u_s(r\mathbf{s}) \approx \frac{e^{ikr}}{r} \int_D F(\mathbf{r}') u_i(\mathbf{r}') e^{-ik(\mathbf{s}-\mathbf{s}_0) \cdot \mathbf{r}'} d^3r' = (2\pi)^3 \frac{e^{ikr}}{r} \tilde{F}[k(\mathbf{s} - \mathbf{s}_0)] \quad (30)$$

The scattered field measured in a direction $\mathbf{s}$ therefore gives information about the Fourier components of the field at position $k(\mathbf{s} - \mathbf{s}_0)$; if measurements are made for all directions $\mathbf{s}$, one gets Fourier information on a sphere of radius k centered on $k\mathbf{s}_0$, known as an Ewald sphere of reflection. However, as in the inverse source case, the information on this Ewald sphere is not sufficient to reconstruct the scattering potential $F(\mathbf{r})$. If the scattered field is measured for all directions of incidence $\mathbf{s}_0$ and scattering $\mathbf{s}$, essentially over a continuum of Ewald spheres, one acquires information within a sphere of radius $2k$, known as the Ewald limiting sphere Σ_L . This geometry is illustrated in [Fig. 5](#).

With the Fourier components determined within a 3D volume, it is possible to perform an inverse Fourier transform to determine a bandlimited reconstruction of the scattering object.

As the information on any finite number of Ewald spheres of reflection is insufficient to uniquely reconstruct the scattering object, one would expect that it is possible to make objects which are invisible, or nonscattering, for any finite number of directions of illumination, and this was in fact shown to be the case ([Devaney, 1978](#)). Evidently, as more data is taken, these nonscattering solutions play a correspondingly smaller role in the reconstruction process.

Fig. 5 Illustration of several Ewald spheres of reflection and the Ewald limiting sphere Σ_L .

Phase Retrieval

The discussion so far has been concerned with linear imaging systems, in which the image data has a linear relation to the object data. However, ill-posedness, in particular nonuniqueness, can also appear in nonlinear imaging, and the analysis of such systems is much less straightforward and must be dealt with on a case-by-case basis.

We consider here the so-called phase problem, or the phase retrieval problem, in which an object must be reconstructed from measurements of the image intensity alone. We assume that the object $f(x, y)$ and image $F(u, v)$ are related by a simple Fourier relation, i.e.,

$$F(u, v) = \int_S f(x, y) e^{-i2\pi(ux+vy)} dx dy \quad (31)$$

where S represents the object plane. The intensity of the image is given by $I(u, v) = |F(u, v)|^2$, and we are concerned with determining $f(x, y)$ from this data alone, if possible.

The nonlinear nature of this problem, due to the implicit reconstruction of the phase, results in some unexpected results. One of the most notable and famous is the observation that the problem is nonunique for one-dimensional (1D) systems but typically unique in 2D systems; we now examine how this is possible.

In considering the uniqueness of this imaging problem, we follow the discussion and notation of [Bruck and Sodin \(1979\)](#). The problem is almost certainly nonunique in general, and certain prior knowledge needs to be applied immediately. It is typically assumed that the source distribution is of finite extent and takes on only nonnegative and finite values.

The source is taken to consist of discrete points, represented by Dirac delta functions,

$$f(x, y) = \sum_{j=1}^m \sum_{k=1}^n f_{jk} \delta(x - x_j) \delta(y - y_k) \quad (32)$$

where $x_j = \Delta j$ and $y_k = \Delta k$, with Δ the spacing between points. The image data are then in the form of a discrete Fourier transform,

$$F(u, v) = \sum_{j,k} f_{jk} e^{-i2\pi\Delta(ju+kv)} \quad (33)$$

where for convenience we have used the Fourier transform in the form,

$$F(u, v) = \int f(x, y) e^{-i2\pi(ux+vy)} dx dy \quad (34)$$

The expression (33) may be simplified by writing the complex exponentials as complex variables, namely,

$$z \equiv e^{-i2\pi\Delta u}, \quad w \equiv e^{-i2\pi\Delta v} \quad (35)$$

where z and w lie on the unit circle in the complex plane. In this way, the image data may be represented as a polynomial in z and w ,

$$F(u, v) \equiv p(z, w) = \sum_{j,k} f_{jk} z^j w^k \quad (36)$$

The measured intensity of the image is given by the squared modulus of $p(z, w)$; since $|z| = |w| = 1$, $z^* = z^{-1}$ and $w^* = w^{-1}$, which means that we may write

$$p(z, w) p^*(z, w) = p(z, w) p(z^{-1}, w^{-1}) \quad (37)$$

From basic Fourier theory, we know that any spatial shift in the overall object position by $s\Delta$ along x and $t\Delta$ along y will result in the polynomial $p(z, w) \rightarrow p(z, w) z^s w^t$. The same argument applies to the measured intensity. We define the autocorrelation polynomial of the image as

$$Q(z, w) = p(z, w) p(z^{-1}, w^{-1}) z^m w^n \quad (38)$$

The additional powers $z^m w^n$ make this a true polynomial, unlike the product of Eq. (37), which will possess positive and negative powers of z and w . As noted, however, the additional powers only modify the object by a trivial spatial shift.

Let us now consider the 1D phase problem, in which the object is $f(x)$ and the image polynomial is of the form

$$p(z) = \sum_{j=0}^m f_j z^j \quad (39)$$

with $f_j \geq 0$. By the fundamental theorem of algebra, any such polynomial may be factored into a product of m terms,

$$p(z) = \prod_{j=1}^m (z - z_j) \quad (40)$$

With the constraint that the $f_j \geq 0$, the zeros z_j of this polynomial must either satisfy $\text{Re}\{z_j\} \leq 0$ and $\text{Im}\{z_j\} = 0$, or must come in a complex conjugate pair, i.e., if z_j is a zero, then so is z_j^* . This must be the case because the coefficients f_j will feature every combination of products of the z_j 's.

With this in mind, the autocorrelation function may be written as

$$Q(z) = \prod_{j=1}^m (z - z_j)(z - z_j^{-1}) \quad (41)$$

and we note that the phase problem may be stated as determining the coefficients f_j from the values of this autocorrelation function, or equivalently determining the z_j 's. The function $Q(z)$ is found by direct measurement, but it features both z_j and z_j^{-1} as its zeros. If all $|z_j| = 1$, then both z_j and z_j^* must be zeros of the polynomial $p(z)$; the solution is uniquely determined. If all $|z_j| \neq 1$, then it is not possible from the autocorrelation function to determine if a measured z_j or its inverse is the true zero of the polynomial $p(z)$. Since there are two choices for each of the zeros, there are 2^m possible solutions for $p(z)$ for the given $Q(z)$ —the solution is nonunique. If there are r zeros with $|z_j| = 1$, then there will be 2^{m-r} possible solutions, and the solution is still nonunique. In general it can be seen that the phase problem is nonunique in 1D.

For the 2D case, however, the situation is quite different. This arises from the fact that the polynomial $p(z, w)$ cannot be represented in a factorized form,

$$p(z, w) \neq \prod_{j,k} (z - z_j)(w - w_k) \quad (42)$$

If it could, we could make arguments similar to the 1D case to prove nonuniqueness. It is very easy, though, to find examples which do not satisfy Eq. (42). For instance, the polynomial

$$p(z, w) = z^2 + w^3 \quad (43)$$

cannot be written in the form of Eq. (42). Without factorization, the earlier nonuniqueness argument breaks down. This alone does not demonstrate that the problem becomes unique, but experimental and computational studies have shown that it is generally so. Of course, in the rare case that the image polynomials can be factorized, uniqueness will fail.

Reconstruction of the phase can be done in many cases by the venerable algorithm of [Gerchberg and Saxton \(1972\)](#), though this method also runs into issues of nonuniqueness when the data possesses certain symmetries.

View Angles of Liquid Crystal Displays

Huang-Ming Philip Chen, National Chiao Tung University, Hsinchu, Taiwan

© 2018 Elsevier Ltd. All rights reserved.

The viewing angle of liquid crystal displays is defined as the maximum angle at which a display panel can be viewed within acceptable visual performance when a contrast ratio exceeds the minimum ratio of 10:1. The viewing angle is measured from one position to the opposite direction, which gives a maximum of 180° in one axis. Four viewing angles need to be taken into account: the horizontal (0°), vertical (90°), and $\pm 45^\circ$ axes. The detail measurements can be performed either by hand or by a conoscope at smaller increment degrees. The contour data mapping exhibits the viewing angle and viewing cone in displays. The narrow viewing angle of twist nematic liquid crystal displays (TN LCDs) is an intrinsic issue of LCDs due to the various retardation changes that are associated with LC molecular motion under electric field, also known as birefringent mode. The contrast ratio is reduced by the light leakage at oblique angle caused by elliptical polarization states. Two major approaches have been applied side by side to solve the issue. One approach is working on optical compensation films to compensate polarization loss in LC cells (Mori *et al.*, 1997). The other is dedicating in LC driving modes and pixel designs to achieve spatial effect in different viewing angles, such as In-Plane-Switching (IPS), or Multi-Domain Vertical Alignment (MVA) modes. Due to the manufacture limitation, both approaches need to work closely to achieve desired wide viewing angle LCDs. In addition to the enhancement of viewing angle in LCDs, many new optical designing concepts have been proposed and realized in the latest researches beyond the aforementioned framework to control the viewing angles that fit the specific needs of display applications.

Optical Compensation Film

The key of designing optical compensation film is based on the LC device in a particular driven state, which is associated with the birefringent mode in LC optics. When the linear polarized light passes through the LC medium, it also loses its linear polarization state and turns into elliptically polarized light. The long axis of elliptically polarized light does not closely follow the local LC director. The light leakage occurs when elliptically polarized light passes through the second polarizer (or called analyzer) at oblique angle. The polarization states of oblique angle can be calculated and mapped on the surface of a Poincaré Sphere. The calculation of correction leading to the linear polarization point can be applied as an optical compensation (Zhu *et al.*, 2006). The directors' profile is taken into consideration when designing the optical compensation film accordingly. It is important to note that this compensation method cannot resolve all viewing angle issues, especially in the gray-scale inversion, which requires divided pixels in domains with different orientations. A pixel divided into two domains may provide a significant reduction in the gray-scale inversion. A pixel that splits into four domains can give relatively symmetrical appearances to improve both gray level and contrast in a panel.

An optical compensation film (or so called Wide View film) is characterized by its refractive indices n_x , n_y , and n_z , in which n_z is the refractive index in the direction perpendicular to the film; n_x and n_y are the in-plane at X and Y axis. In order to compensate an on-state of TN LCD, an axial symmetric compensator with negative birefringence ($n_x = n_y > n_z$) can be applied. In general, the compensation films can be classified by its optical characteristic, such as A, C, O-plate, and biaxial films. Based on the specific manufacture processes, these films can also be described, as stretching films, or LC coated films.

	<i>A plate</i>	<i>C plate</i>
Positive (+)	$n_x > n_y = n_z$	$n_z > n_x = n_y$
Negative (-)	$n_x = n_z > n_y$	$n_x = n_y > n_z$

Many references have indicated the viewing angle issues can be solved by various optical compensation films for different LCD modes. In general, the viewing angle of TN LCD mode can be compensated by bend-splay hybrid orientation discotic material coated films. The viewing angle of MVA mode can be compensated by either biaxial film itself or positive A (A^+) plate in conjunction with negative C (C^-) plate. The IPS mode, on the other hand, requires either negative A (A^-) plate or positive C (C^+) plate to enhance its viewing angle. The complex structures of compensation films (i.e., multiple optical composite layers) were proposed in some reports to solve the finite polarization deviation in the LC cells. These calculated solutions may be unrealistic when facing limited manufacturing ability or rising costs. The Fuji film Corporation (Ito *et al.*, 2013) has revealed their significant Wide View film (WV film) development in 2013 (Ito *et al.*, 2013). The hybrid alignment of polymerized discotic materials is the main component of compensation film for TN LCDs. The grayscale inversion can be significantly minimized because the LCs' director in the middle of the cell is parallel to the axis of the polarizer. The retardation of the LC has least transmittance effect when the darker gray level moving to the brighter gray level. As a result, controlling the orientation of polymerized discotic materials is the key to formulate new WV films in improving the TN-LCDs' gray scale image qualities. In addition, they also developed a precise patterning chemical method by using one shot of non-polarized UV light to control and create patterned discotic alignments. The resulting film is called film patterned retarder (FPR) with out-of-plane retardation (R_{th}) close to 0 nm. The advantage of FRP is to reduce the oblique cross-talk in 3D display applications. Furthermore, the achromatic quarter wave films can be prepared by coating the rod-like LC layer on top of the polymerized discotic materials. Their achromatic quarter wave film measurement outcome suggests that the retardation is similar to the ideal curve below 550 nm. The deviation is much smaller than one-film type achromatic quarter wave film in the range of 550–650 nm. This new achromatic quarter wave films are great assets to LCD as well as to OLED for the true black appearance.

The optical isotropic Blue Phase LCD is assumed to have a good dark state and high contrast ratio in theory. The undesired light leakage occurs in the voltage off-state. Wu *et al.* explains that the causes of the dark-state light leakage are coming from the edge of protrusive electrodes, polarization rotation effect of BPLC material, and scattering from polymer network (Liu *et al.*, 2014). In this article, it states that the major source of light leakage comes from the polarization rotation effect in the dark state. Fortunately, this light leakage can be compensated by the Poincaré Sphere method. There are three major solutions using compensation films to suppress light leakage for the polarization rotation effect: (1) Small angle rotation of analyzer with biaxial film compensates the light leakage. This method can only reach the contrast ratio as high as 3700:1 in the normal direction. This simple approach faces more challenges when one wishes to further improve the contrast ratio through compensation. (2) Utilizing broadband and wide view circular polarizers to compensate the light leakage is proposed by Hong. The contrast ratio at normal direction can be as high as 12,000:1; and the viewing angle can be as wide as the entire viewing zone (CR 100:1). This approach requires that the two layers of biaxial films to form one circular polarizers for one side. Consequently, there are four layers of biaxial films that need to be aligned in order to obtain good results. The complicated film alignments may hinder one to apply this method for compensating the light leakage. (3) Using dispersive positive A (A^+) film is another method to compensate the light leakage. The birefringence of dispersive positive A film is designed to vary from 450 to 650 nm, for example: 0.008 for 450 nm, 0.005 for 550 nm, and 0.004 for 650 nm. The last method which requires not only dispersive positive A film, but also biaxial films is the same method as (1) and (2). The result of BPLCD can reach contrast ratio at normal direction as high as 13,500:1 with relatively wide viewing zone.

The flexible LCDs research becomes much more active recently in competing with the flexible OLED devices. The capability of flexible LCDs remains challenged. Many research groups have turned their attentions toward the enhancement of the optical performance that may exclusively occur in the flexible LCD. Ishinabe *et al.* (2014) published the article indicating that the contrast ratio of 650:1 and a wide viewing angle of 150° based on polycarbonate substrates in 2014. Jeong *et al.* (2016) attempted to eliminate the bending-induced retardation of a plastic film by coating polystyrene (PS) or poly (methyl methacrylate) (PMMA) on the polycarbonate substrates. The negative birefringence of the coated PS or PMMA layer is formed when bending the polycarbonate substrates. As a result, the bending-induced retardation from polycarbonate substrate can be compensated. Oka *et al.* (2016) (Japan Display) revealed their design using the polyimide (PI) and acrylic resin layers as C^+ -plate to compensate their flexible FFS LCD in 2016. The retardation can be controlled by the thickness of PI layer. The positive C (C^+)-plate ($R_{th} = -450$ nm) can be reached when PI is at 3.4 μm in thickness. A 2.95-in. prototype sheet LCD with contrast ratio of 860:1 in 400 μm panel thickness was demonstrated.

Improvement From LC Modes

Various nematic LC modes have been proposed and realized for the wide view liquid crystal displays. Hitachi manufactured the first super-TFT liquid crystal display (was later called In-Plane-Switching (IPS) mode) to enhance the viewing angle back in 1996. It was evolved from IPS mode to super IPS (S-IPS) mode to solve the color shifting issue in 1998, followed by the advance super IPS (AS-IPS) to enhance the transmittance in 2002. In order to solve the aspect ratio, transmittance, and contrast issues, the concept of Fringe Field Switching (FFS) was proposed by Lee in 1998 and was put into mass production of the IPS-Pro LCD TV

(as the abbreviation of IPS-Provectus) at the end of 2004. The FFS mode has over 3 times of higher contrast and 1.5 times of higher transmission than original IPS mode. Besides the electrode design, the optical compensation films still require for IPS or FFS modes to further enhance their viewing angle at $\pm 45^\circ$ and $\pm 135^\circ$. Due to the high demand of portable LC devices, p-FFS and n-FFS were proposed by using positive (p) and negative (n) dielectric LC materials. The pros and cons between p-FFS and n-FFS were mentioned by Wu (Chen *et al.*, 2015). In short, p-FFS gains the response time, yet n-FFS achieves the higher transmittance. Both have excellent viewing angle and minor color shift. The n-FFS has smaller image flicker, but it needs a 2D electrode patterned design to suppress its grayscale inversion.

Multi-Domain Vertical Alignment (MVA) liquid crystal display using negative dielectric LC to achieve wide view display was first developed by Fujitsu in 1997. The protrusion electrode divided one pixel into 4 domains. Single sided protrusion and the open slit on the counter side MVA structure was announced to achieve similar effect in 1999. AU Optronics revealed their AMVA with fast pixel response times yet small brightness changes. Their second generation of AMVA (AMVA II) was presented with the improved contrast ratio to 2500:1 in 2006. In 2009, the third generation Advanced MVA III (AMVA III) was developed to fulfill the high quality image and fast response time. The AMVA III adopted the new cell process based on polymer sustained alignment (PSA) process and new pixel electrode pattern design without protrusion and ITO main slit. Moreover, 8-domain pixel electrode pattern with new ART (additional refreshing transistor) architecture was implemented to gain the precise control in the lower levels of gray scale. As a result, a 46-in. AMVA III LCD can obtain contrast ratio greater than 8000:1 with 180° viewing angle (Chen *et al.*, 2009). It is notable that Samsung Electronics Co. Ltd. received a Gold Award for their 40-in. High Contrast, Wide Color Gamut, LED-Backlit LCD TV at the 45th annual Society for Display (SID) 2007 exhibition. This prototype LED TV featured a dynamic contrast ratio of 10,000:1 and claimed its viewing angle at 180° in all direction. MVA has superior viewing angle, good dark state, color reproduction, and fast response time. Comparing to IPS mode, the optical compensation film of MVA mode is much easier to reach its high contrast ratio and wide viewing angles. As a result, MVA mode dominates the TV market lately.

Another multi-domain VA LCD approach is called Axially Symmetric Vertical Alignment (ASVA) mode with circularly symmetric at 360° viewing angle. It was first proposed as the Axis Symmetric Micro-Cell (ASM) method by Yamada *et al.* (1995). Axis symmetry micro-cell (ASM) is fabricated by phase separation of liquid crystal and polymer wall, in which the LC molecules are surrounded by polymer walls under UV irradiation. The chiral compound is added to ensure nematic liquid crystal with a 90° twisted orientation. The ASM method has the advantage not only wide viewing angle due to the symmetry orientation axis, but also disclination-free due to the mono-domain orientation. They continue to develop a negative dielectric liquid crystal in the ASM (N-type ASM) mode in 1998. The N-type ASM mode combined with compensation film is able to reach 300:1 contrast ratio and over $\pm 80^\circ$ viewing angle. The difference between P-type and N-type is that axially symmetrical direction and tilted angle are set prior to carrying out the final curing of UV irradiation. The only drawback is the response time falling around 30 ms. They proposed the ASVA mode with multiple protrusion structures to define the plurality of liquid crystal regions in 2001. Liquid crystal molecules in the plurality of liquid crystal regions are aligned axially and symmetrically around an axis perpendicular to the surface. Each region is approximately a square of 70 μm .

In addition to IPS and MVA modes, researchers have continually improved the image quality by all means. Optically compensated bend (OCB) mode is known to possess the advantages of wide viewing angles and fast response time over nematic liquid crystal displays. It was modified from the original pi-cell (proposed by Bos and Koehler/Beran, 1984) to a much thinner cell gap with optical compensation films by Yamaguchi *et al.* (1993). Bos *et al.* proposed using a negative birefringence film with the optic axis in the normal direction (negative C-plate) to compensate the pi cell in 1993. Yamaguchi *et al.* (1993) suggested the use of a biaxial film for optical compensation of the OCB cell. The viewing angle performance, however, was not satisfied by these compensation methods. Mori offered the OCB-WV film consists of a hybrid polymerized discotic material layer alignment (as in TN WV film) with biaxial film to suppress the light leakage in the on-state of bend mode (Mori, 2005). Chen *et al.* proposed using reactive monomer to suppress the splay-to-bend transition (i.e., bias-free OCB mode) in 2009. The thin splay orientation of LC polymer layer not only provides the surface pre-tilted angle to suppress the splay-to-bend transition, but simultaneously becomes an inner-retarder to minimize the light leakage. The contrast ratio is improved up to a factor of 11 without using compensation films (Chen *et al.*, 2009).

The Latest Approaches of Wide View Angle LCDs

The latest approaches are focused in the optical structure design to enhance LCD's viewing angle after 2010. The design implements a diffuse optics on top of LCD. Kälantär reported the concept of shaping the luminance cone and making spatially uniform

luminance by a light scattering film in SID Symposium 2011. A directional backlight with a narrow angular luminance distribution was applied in the backlight unit. The result suggested that the normal and oblique contrasts were enhanced by a factor of 1.1 and 6 on the VA panel; and 2.5 and 2.7 on the TN panel, respectively. The imaging blur and low intensity were the main drawback of using conventional diffusing film. Yamamoto *et al.* (2014) recommended microstructure film to control passing light on top of LCD in 2014. The microstructure film consists of plate-like transparent polymer and the black dots were randomly arranged on the base film. The cone shape air cavities were placed beneath the black dots to control the passing light. Their result suggested that the microstructure film has over five times higher contrast ratio than the conventional diffusing film. In a similar way, Yang and Chen proposed photo-luminescent LCD with R, G, B-quantum dots (QDs) on top of the conventional TN LC cell to improve the LCD viewing angle in 2016. In particular, the single wavelength excitation at 410 nm gives the great advantage for LCDs without considering the retardation dispersion. Thus, the higher contrast ratio at normally black mode achieved $\pm 70^\circ$ viewing angle (CR>10:1) and 3 ms under 4 V driving voltage in the QD array over TN-LC (Yang *et al.*, 2016).

Controlled Viewing Angle of LCDs

The criticism of the viewing angle has been raged over the years when TN LCD first appeared in the market. The issues of viewing angle are mostly attributed to the unique birefringent mode controlling the light intensity between crossed-polarizers. Wide viewing angle (WVA) LCDs dominate the display market. However, the narrow viewing angle (NVA) or dual-view LCD is getting its popularity for security, personal privacy, or safety reasons. The birefringent mode is more prominent for designing the directional viewing control system. A number of approaches have been realized in the controllable viewing angle LCDs. The double-cell architecture is the first proposed method, in which one additional liquid crystal panel is placed on top of the main panel to control the viewing angle (Jeong *et al.*, 2007). It is the simplest approach, but suffers from the panel thickness and greater costs. The second design is subpixel divided method, in which each pixel is divided into two domains: the primary pixel domain is for displaying images whereas the sub-pixel domain is to control the viewing angle (Lim *et al.*, 2010). The third method is to adopt dual light sources in conjunction with two light-guided films in the backlight system without changing the design of LC panel. The resulting controllable LCD is able to obtain the viewing angular ranges from 140° to 60° (Chien *et al.*, 2006). The fourth is based on a HAN (hybrid aligned nematic) cell, driven by fringe- and vertical-electric fields (Jeong *et al.*, 2008). The viewing angle in the horizontal direction can be controlled from 120° to about 20° . The last method, but not the least, is utilizing a patterned vertical alignment LCD (PVA-LCD) with the circular polarizers. The WVA mode is turned on when no bias voltage on the common electrode. A bias voltage (2.42 V) is applied on common electrode to turn on the NVA mode. The contrast ratio of WVA mode is more than 100:1 in all viewing angles. The viewing angle can be reduced to 20° when the NVA mode is turned on (Yu *et al.*, 2014).

Dual-view liquid crystal display is able to simultaneously deliver different information in the right and left viewing directions, i.e., two distinct viewing cones for right and left directions. After SHARP launched "Dual View LCD" technology in 2005, the dual view display technology was soon adopted by the automobile makers, in their concept cars. There are several approaches have been realized in the dual-view LCD. One of the approaches is to create spatial-multiplexing type, in which the main pixel of the DV LCD contains both a right and left sub-pixel. Parallax barriers and lenticular lenses are commonly applied to direct light from different pixels to achieve the intended field of view. Controlling the viewing angles of the right sub-pixel (RSP) and the left sub-pixel (LSP) can be fulfilled by two different tilted surfaces in one pixel, or by patterned electrodes, in which it provides the inclined electric field to control the LC direction. The other approach is based on the time-multiplexed type, which uses the directional backlight module with complex reflectors and fast response LC cell, such as OCB, Blue Phase modes. The negative aspect is that the aperture ratio is decreased as a result of the dead zones formed nearby the electrodes. In 2017, Chen *et al.* proposed a two-domain twisted nematic liquid crystal with a patterned E-type polarizer which is capable of suppressing the crosstalk between right and left views. The crosstalk is successfully lowered to less than 0.07% for all gray levels, while keeping the viewing angle around 50° for both left and right views (Chen *et al.*, 2017).

Summary

Viewing angle is an intrinsic matter of LCD associated with its birefringent mode optics. It has been intensively studied to achieve wide viewing angle for monitor and TV applications. The methods such as optical compensation films, pixel designs, and driving modes are available to resolve the negative viewing angle issues. Since Samsung succeeded in delivering the widest viewing angle in 2007, the viewing angle is no longer a critical issue in LCDs. It is possible to extend the viewing angle in all directions based on fulfilling the minimum contrast ratio 10:1 requirement. On the contrary, the small viewing angle of LCDs becomes a benefit when one needs to control and manipulate as needed, especially, for privacy purposes. Thus, the latest developments of alternating maximum and minimum viewing angles are valuable traits in LCDs.

Introduction

Organic light-emitting diode (OLED) with its superb attributes in thinness, light-weight, brightness, color, dynamic contrast, viewing angle, response time, power efficiency and form factor has been declared as the “ultimate display” of our time. It is an emissive device with a very simple structure which comprises a stack of extremely thin layers ($<0.2\ \mu\text{m}$) of organic materials sandwiched between two electrodes. The anode which is usually made of a transparent semi-conductor of high work function (e.g., ITO) is capable of injecting holes into the organics while the cathode often selected from a highly reflective metal of low work function (e.g., Li, Ca, Mg, LiF/Al) is capable of injecting electrons. If the corresponding adjacent organic layers are chosen properly with a set of matching highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) and applied a positive bias voltage (DC driven), the injected electron and hole are transported to recombine near the heterojunction of the corresponding electron/hole transporting layers (ETL/HTL) to produce exciton, from which light emission will occur and emit through the ITO/glass. The color of the emitted photon will roughly correspond to the bandgap energy of the organic luminescent material with an internal quantum efficiency (η_{INT}) governed by the equation of ($\eta_{\text{INT}} = \gamma \cdot \eta_r \cdot \psi_{\text{PI}}$), where γ is the probability of carrier recombination (e/h ratio), η_r is the efficiency of exciton production and ψ_{PI} is the photoluminescence quantum efficiency. Electro-generated excitons statistically have a ratio of singlet/triplet ratio about 1/3. Abided by *Pauli* exclusion principle, only singlet is spin-allowed to efficiently transition radiatively to its ground state for most fluorescent materials while the spin-forbidden decay of triplet (phosphorescence) is usually too slow nor efficient to be useful. It follows that the theoretical limit of η_{INT} is limited to only about 25% without the capability of harvesting the triplet exciton. Moreover, as a Lambertian source, not all the light generated within OLED can escape out of the planar cell through various layers of media with different refractive index (n), for there is a further loss which can be estimated by the Fresnel equation of $\alpha = 1/(2n^2)$. Therefore the external quantum efficiency (η_{EXT}) can be further calculated by the equation of ($\eta_{\text{EXT}} = \alpha \cdot \eta_{\text{INT}}$) where α is designated as the out-coupling efficiency which without means of any light enhancement is about 20% for most organic materials with an average $n \approx 1.5 - 1.9$. Lastly, the power efficiency which is inversely proportional to the driving voltage must also be considered in order to meet the ever increasing demand of high resolution mobile displays. To drive down power consumption by minimizing carrier injection barriers and increasing the probability of recombination near the interface, a typical bottom-emission OLED architecture of today is shown in [Fig. 1](#) (top) with the addition of several key functional organic layers such as electron injection layer (EIL), hole injection layer (HIL) and a R,G,B doped emitter to control color of emission.

Over the last 15 years, tremendous progress has been made in OLED materials overcoming the limitation of η_{INT} of fluorescence which has been enhanced to nearly 100% by exploiting phosphorescence as well as delayed fluorescence. Power efficiency can also be boosted by the discovery of bipolar host material and the introduction of extremely electron deficient (*p*-) and donating (*n*-) dopants into the respective HTL and ETL to increase its conductivity as illustrated in [Fig. 1](#) (bottom) with a typical *p-i-n* OLED energy diagram with its LUMO and HOMO bending after applying a positive bias voltage. Tandem OLED to increase luminance without increasing drive current density nor jeopardizing OLED lifetime and light enhancement technology have also been developed to extract more light out of OLED with the understanding of its optics. As a result of these discoveries, the most eco-friendly, sun-like area luminaire of indoor OLED lighting has now become possible.

Materials

Early OLED materials development has all been focused on the design and synthesis of fluorescent molecules which can only harvest singlet excitons. In the first decade of 21st century, unusually high EL efficiency and lifetime have been reported for a number of blue fluorescence OLEDs, many of which are anthracene-derived fluorophores, such as non-dopant deep blue emitter TAT with $\lambda_{\text{max}}^{\text{EL}}$ 444 nm, CIE_{x,y} (0.16, 0.09), (η_{EXT} 7.18%) and doped sky-blue emitter of arylamine-substituted distyrylarylene DSA-Ph with $\lambda_{\text{max}}^{\text{EL}}$ 465 nm, CIE_{x,y} (0.15, 0.29) in MADN host (η_{EXT} 8.7%). In depth study of TAT has revealed that both triplet-triplet annihilation (TTA) and the outcoupling enhancement by dipole orientation of emitting molecules contribute to the production of singlet exciton from which exceedingly high η_{EXT} is thus achievable.

Major breakthrough of EL efficiency of OLED started to emerge before the end of last century. One of the early examples was a green phosphorescence material known as $\text{Ir}(\text{ppy})_3$ which is an organometallic-based coordination complex containing heavy metal Iridium. Utilizing the heavy atom effect that promotes spin-orbital coupling, these 2nd generation luminescent materials all possess a hybrid emissive excited state of singlet and triplet excitons with a rather short excited-state lifetime (in μs) thus easing up the forbidden phosphorescence at room temperature. Based on this emissive mechanism, numerous heavy metal containing

Fig. 1 A typical bottom-emission OLED architecture (top) and energy profile of *p-i-n* OLED upon positive bias (bottom).

(mostly Ir) red, green or even some light blue phosphorescence EL materials have been reported. Meanwhile, hosts derived from carbazole with high triplet energy as well as many triplet exciton blocking materials to prevent luminescence quenching have also been developed. In dopant/host emitter device with appropriate blocking layer, EL power efficiency of >100 lm/W for green $\text{Ir}(\text{ppy})_3$, >25 lm/W for red $\text{Ir}(\text{mphpq})_2(\text{acac})$ equivalent to $\eta_{\text{EXT}} \sim 25\%$ and near 50 lm/W for sky-blue FIrpic was reported at brightness of 1000 cd/m^2 . Mainly due to the high EL efficiency (hence low power consumption), today's AMOLED display products in the marketplace all have adopted phosphorescence EL materials for their green and red emitters. The blue phosphorescent material owing to its intrinsic instability and lack of color saturation issues remains to be the *Holy Grail* that has been pursued relentlessly. As a result, display industry presently favors the use of the deep blue anthracene-based fluorescent materials especially the deep blue with $\text{CIE}_y (<0.10)$ as dopant for its AMOLED products.

The 3rd generation of luminescence was discovered in 2011 which is based on the up-conversion of triplet exciton into its singlet excited state leading to efficient thermally activated delayed fluorescence (TADF). This type of materials which have the advantage of containing no heavy metal like Ir or Pt (which is expensive and rare) and the potential of harvesting triplet exciton as well as the possibility of breaking the Ir-materials patent gridlock have quickly caught the fancy of a great many researchers. In just a few years thereafter, green 4CZIPN ($\lambda_{\text{max}}^{\text{PL}}$ 507 nm) and DACT-II ($\lambda_{\text{max}}^{\text{PL}}$ 516 nm), greenish blue ($\lambda_{\text{max}}^{\text{PL}}$ 480 nm) *SpiroAC-TRZ* and a near blue ($\lambda_{\text{max}}^{\text{PL}}$ 460 nm) *DMAC-DPS* with $\text{CIE}_{x,y}$ (0.16, 0.20) have been reported to achieve η_{EXT} as high as 19.3%, 29.6%, 36.7% and 19.5%, respectively. All these TADF materials have a common structural feature containing a twisted non-coplanar configuration formed by steric crowding between an electron donor (usually arylamine) and an acceptor (e.g., CN, SO_2 , $\text{C}=\text{O}$, $\text{P}=\text{O}$) through certain π -conjugation (such as benzene ring) which has been shown to possess unusually narrow singlet-triplet state bandgap (<0.1 eV) conducive for room temperature intersystem crossing.

In 2015, a series of TADF molecules have been adopted as an assisted dopant (such as ACRSA) in OLEDs to transfer its singlet excitons to the singlet state of a more fluorescent dopant emitter (such as *TBPe*) via Förster energy transfer process to produce what is called "hyperfluorescence". To differentiate from TADF emitter, a 3.5th generation of OLED materials has been declared after its discovery which opens up a golden opportunity for further research in the pursuit of highly efficient yet still stable emitters particularly for the blue color. This is because the twisted molecular configuration associated with TADF molecules usually have a rather large FWHM which is adverse to the color purity required for display applications. Utilization of conventional fluorescence molecule as the end emitting dopant can alleviate the problem so as to regain its color purity yet still maintain high EL efficiency as well as long device lifetime. Although TADF materials are non-heavy-metal containing, recent study showed that most TADF OLEDs still suffered from fast degradation and "roll-off" of efficiency at high brightness particularly acute for the blue. This is mainly attributed to the synergetic oxidation of the TADF emitters in the devices, including at least an electrochemical oxidation and a photo-oxidation processes. Evolution of OLED materials development and a few examples of key molecular structures are illustrated in Fig. 2.

Fig. 2 Evolution of OLED materials development and examples of key molecular structures.

Devices

All good OLED materials invariably need good device architecture to maximize their electroluminescence (EL). This is particularly true in regard to overall performance involving key measurement parameters like stability, power consumption, luminance efficiency and color. OLED device structures can be roughly classified into bottom-emission and top-emission (TOLED) depending upon whether the bottom anode (ITO) or the top cathode is made transparent (with its anode reflective), respectively. If both electrodes are transparent, a *transparent* OLED can also be made. For certain *n*-type TFT driving needs, there have also been developed the corresponding bottom-emission and top-emission *inverted* OLED where the anode and cathode are reversed instead.

For driver electronics, there are passive-matrix (PM-OLED) used mostly for low-information content, small size alphanumeric displays (because of its line-by-line scan requiring very high peak-current density and limitation for high resolution) and the active-matrix TFT driving (AM-OLED) which is the most popular. Low temperature poly-silicon (LTPS) TFT with its high *p*-channel mobility ($\sim 100 \text{ cm}^2/\text{V s}$) is best suited for small to medium displays like the smartphones and tablets while Oxide (IGZO) TFT is particularly suitable for large size displays like OLED TV. To increase the aperture ratio for high-resolution, it is most advantageous to couple LTPS-TFT backplane with a TOLED structure in which its cathode is made semi-transparent (e.g., Ag:Mg 15 nm) and its

Fig. 3 Microcavity effect of TOLED (top) and a typical tandem OLED structure (bottom).

anode reflective (Ag) as exemplified in Fig. 3 (top). There's also an added advantage in its capability of creating a microcavity within the organic media between the two metallic electrodes one of which is semi-transparent and the other reflective. Its optical effect in terms of constructive (*antinode*) and destructive (*node*) interferences which can be modeled as a Fabry-Perot cavity embedded light source within 2 mirrors, is the dramatic spectral narrowing and intensity enhancement commonly observed in a TOLED. By clever adjustment of the optical length L of the μ -cavity (which is usually done by adjusting the HTL to minimize impact on drive voltage) for each of the color pixel according to the first order approximation of $[2L/\lambda_{\max} + \phi/2\pi = m]$ (m =integer) and [full width at half maximum ($FWHM$) = $\lambda^2/2L \times 1 - (R_1R_2)^{1/2}/\pi(R_1R_2)^{1/4}$] where L is the optical length and R_1R_2 are the reflectance of the 2 mirrors, greatly enhanced color gamut by reducing FWHM of each of the R, G, B emission wavelength (λ) and EQE (η_{EXT}) of AM-OLED can be readily achieved.

Another key development in OLED device is the discovery of tandem OLED where multiple OLEDs can be coupled together by transparent connecting charge-generation layer (CGL) which functions as a reversed p/n degenerate contact to create and inject electron and hole back to the ETL and HTL, respectfully for recombination as depicted in Fig. 3 (bottom). As a consequence, luminance of tandem OLED (L_n) can be enhanced at the same driving current density according to the equation of $[L_n = n \times L]$ where n is the number of stacked units and L is the luminance of each single unit. This in turn means that the lifetime of tandem OLED can also be greatly enhanced because the intrinsic stability of organic luminescent materials is singularly dependent upon the driving condition and inversely proportional to the total amount of electric charge passed through the device. Thus, brightness of 3000 cd/m² required for most general indoor lighting is readily attainable with relatively small driving current density.

Recently, due to the high interest of developing OLED as a green and healthy *area* indoor solid state lighting alternative to LED, a great deal of effort has been aimed to extract more light trapped inside OLED. Detailed analysis by rigorous electromagnetic modeling of optics have revealed 4 types of light entrapment, namely radiation mode, substrate mode, waveguide mode and Plasmon mode as depicted in Fig. 4 (top). It also shows that coupling into different modes is highly dependent on the position of emission center which oscillates as illustrated in Fig. 4 (bottom). The second *antinode* appears to give the highest outcoupling efficiency while the surface Plasmon mode can be minimized by fabricating OLED emitter away from its reflective metallic electrode. To date, the most noteworthy light extraction technology is the so-called internal enhancement layer (IES) which is a high-index coupling layer embedded with light scattering particles incorporated in-between the ITO and the glass substrate where η_{EXT} as high as 45% has been achieved in white OLED.

Applications

As display technology, OLED has considerable attributes that are unsurpassed by others. There have been a great many super AMOLED products (e.g., smartphones, tablets, monitors, VR/AR microdisplays, wearables, TVs, etc.) that have successfully entered the consumer electronics market and indeed, many of which had won Best Display Awards (including most recently the 2016 "Best of Innovation" for a 77-in 4K OLED TV). It has also been declared "the best panel ever" as tested by the independent Display Mate Labs in major measurements categories like winning the "highest color accuracy, infinite contrast ratio, lowest screen reflectance, and smallest brightness variation with viewing angle."

Fig. 4 Electromagnetic modeling of light generated inside OLED (top) and their couplings with respect to the position of emission (bottom).

Fig. 5 Examples of OLED displays and lighting.

As predicted by DisplaySearch and IHS, OLED display revenues will grow to about \$44B in 2020 in which LTPS-TFT AMOLED smartphones will be the main driver overtaking TFT-LCD to become the leading display technology in mobile sector while OLED TV business will begin to grow significantly after 2016. In addition, owing to the tremendous improvement of power efficiency ($> 100 \text{ lm/W}$) as well as lifetime recently, WOLED lighting which has the potential of emitting warm light across large surfaces

and bringing to bear novel *form factor* into the lighting sector is also forecasted to gain market share slowly and eventually to become competitive with the existing LED solid state lighting particularly in indoor illumination. A glossary of several OLED display and lighting products is reproduced in Fig. 5.

Perspectives

After more than 30 years of R&D, OLED technology has finally begun to hit the big time in the display market. It is expected that flexible OLED (FOLED) will be a “killer application” for which OLED industry has long been searching. Indeed, we have witnessed the successful launching of many unbreakable and bendable FOLEDs which are fabricated on thin plastics and continue looking forward to the ultimate realization of foldable and rollable OLEDs in years to come. But in order to become a viable and sustainable business to compete effectively with LCD as well as a host of other new emerging displays like those of Quantum Dot, microLED and laser, many challenges must be overcome. These include issues of deep blue emitter efficiency and lifetime, large area fabrication, mass production, cost down, thin-film encapsulation, robust RGB pixelation (to achieve high yield and resolution), improvement of luminance and power efficiency, etc. Control of optics to maximize out-coupling efficiency of OLED (without impacting on image quality for display application) will remain to be an interesting topic of research and further study in the future.

It suffices to state that the future of OLED as display and lighting is extremely bright and colorful, which presents great opportunities for numerous invention and innovation in R&D as the technology matures and continues to improve over time. We will witness significant growth of OLED investment and business as well as proliferation of AMOLED, FOLED, wearable and VR/AR products like smart phones, PMP, tablets, ultrabooks, monitors and TVs in the marketplace in the foreseeable future. By then, it is predicted that many area OLED lighting luminaire products will also be with us as one of the major green, energy-saving, most healthy (no glare nor blue-light hazard) solid state lighting fixtures in our home. Perhaps, the last question to be pondered is: Will Roll-to-Roll printing of OLED not be too far?

It is impossible to describe OLED science and technology in any breath or depth in these few pages. Interested readers are encouraged to read further with the list of books and references cited in the following.

Optical Characteristics of Display Devices

Han-Ping D Shieh, National Chiao Tung University, Hsinchu, Taiwan

Definition of a Display

A display can be defined as an object that transfers information to the viewer and/or an output unit that gives a visual representation of data (Lee *et al.*, 2008; Yeh and Gu, 2010; Tsujimura, 2017; Kobayashi *et al.*, 2009).

Optical Characteristics of a Display

Considering that the information provided by a display is delivered via light, the optical characteristics of a display are of great importance. A display has, in general, the optical characteristics of luminance, reflectivity, contrast ratio, color, surface gloss, resolution, and image sharpness (sometimes called small area contrast). Measurement methods can be obtained from the Electronics Industries Alliance (EIA) JT-31 (Optical Characteristics of Display Devices), Society of Automotive Engineers (SAE), International Organization for Standardization (ISO), and Video Electronics Standards Association (VESA) Standards, to name a few (see Relevant Website section).

Radiometric and Photometric Units

To measure light, a certain system of units is needed. Generally, the radiometric or photometric units are adopted for different purposes. The radiometric units refer to a measurement of any portion of the electromagnetic spectrum, such as visible, infrared, and ultraviolet light. In this system, the radiant power is in Watt (W), which is the total radiant energy per unit time (Joule per second, J/s). Different from the radiometric units, the photometric units only deal with visible light and consider the human perception. As the sensitivity of the human vision system varies with wavelengths, the weights of different wavelengths are also different. In the photometric system, the most basic quantity is luminous intensity, which is a measure of the wavelength-weighted power emitted by a light source in a particular direction per unit solid angle. The International System of Units (SI unit) of luminous intensity is candela (cd) (in the English system, cp), which is also an SI base unit. Table 1 lists some common radiometric quantities with their units and corresponding photometric quantities with units.

Luminance

The luminance of a display is the output luminous intensity per unit area in a unit solid angle, which is given in units of candela/square meter or cd/m² (in the English system fL), as shown in Eq. (1) and Fig. 1 (Warren, 2007; Wyszecki and Stiles, 1982). Luminance is one of the most important specifications of a display device, which is closely associated with a display's perceptive brightness (Booker, 1981; Ronchi *et al.*, 1980). Generally, a computer monitor may have a luminance of several hundred nits while an outdoor display may have several thousands (Gong *et al.*, 2012; Reinhard *et al.*, 2010). In addition, the luminance may vary with the region on a screen (spatial luminance profile) and viewing angle (angular luminance profile). To measure luminance of a display, a photometer, photometer/colorimeter, or spectroradiometer can be adopted.

$$L = \frac{d\Phi}{d\Omega \cdot dS \cdot \cos\theta} \quad (1)$$

where L is luminance, Φ is luminous flux, Ω is solid angle, S is area, and θ is viewing angle.

Table 1 Common quantities and units in the radiometric and photometric systems

Radiometric system		Photometric system	
Quantity	Unit	Quantity	Unit
Radiant energy	J	Luminous energy	lm · s
Radiant intensity	W · sr ⁻¹	Luminous intensity	cd (lumen · sr ⁻¹)
Radiant flux	W (J · s ⁻¹)	Luminous flux	lumen (cd · sr)
Radiance	W · sr ⁻¹ · m ⁻²	Luminance	nit (cd · m ⁻²)
Irradiance	W · m ⁻²	Illuminance	lux (lm · m ⁻²)

Fig. 1 Calculation of luminance perceived from a direction θ relative to the normal. $d\Phi$, $d\Omega$, and dS are infinitesimal luminous flux, solid angle, and area, respectively.

Illuminance

The illuminance is the total luminous flux incident on a surface, per unit area, as given in Eq. (2) (Warren, 2007; Wyszecki and Stiles, 1982). Its units are lumen per m^2 or lux (and in the English system Ft.cd). This is measured using illuminance meters. The luminance of a display may also vary with the region on the screen.

$$E = \frac{d\Phi}{dS} \quad (2)$$

where E is illuminance, Φ is luminous flux and S is area.

Reflectivity

The reflectivity of a display is the ratio of the reflected light to the incident light. For CRTs, the reflectivity is measured with incident light at 45 degrees, while a smaller angle of 30 degree is used in some cases for LCDs (Keller, 1997). The reflected light from the surface is measured with a detector normal to (perpendicular to) the surface.

Color

A normal human vision system has three kinds of cone cells, which respectively have sensitivity peaks in short (S, 420 nm–440 nm), middle (M, 530 nm–540 nm), and long (L, 560 nm–580 nm) wavelengths. According to the additive color-mixing principle, various color systems have been developed from the working mechanism of the human color vision. With the aid of a color system, although color perception is different from different individuals, the standard responses to a color stimuli can be evaluated and we can measure colors of different objects and display images. Color can be measured with a colorimeter or spectroradiometer (Smith, 1978; Ohno, 2000). The output data are given in various color systems. Color systems, such as the 1931 CIE (Commission International de l'Eclairage) Color System (x, y), the 1960 CIE (u, v) or 1976 CIE (u', v') color coordinates are all used (Wikipedia, 1931, 1960; see Relevant Website section). All these color systems can be converted to each other by simple mathematical relations and these conversions are usually available to the user in the data output. The choice of the color space/system is dependent on application but the system in most general use for displays is the 1976 CIE (u', v'), where the values of u' and v' can be converted from tristimulus values XYZ in 1931 CIE (x, y) by Eq. (3) (Ford and Roberts, 1998). This color system has become more widely used because equally perceived color differences in this color system are at almost equal distances in the color space (McGuire, 1992). In reality, the quest for a system with equal distances equating to equal color differences can be achieved through a complicated matrix approach in which the constants used in the matrix vary from point to point in the color space.

$$\begin{aligned} u' &= \frac{4X}{X + 15Y + 3Z} = \frac{4x}{-2x + 12y + 3} \\ v' &= \frac{9Y}{X + 15Y + 3Z} = \frac{9y}{-2x + 12y + 3} \end{aligned} \quad (3)$$

Gloss

Gloss is a measure of surface reflectivity under Snell's Law criteria (equal incidence and reflection angles). The measurement angles of 20, 45, 60, and 85 degrees are used to measure the gloss of common surfaces (Keller, 1997). Display glass surface measurements tend to use 60 degree gloss angle. The surface of a display can be made rougher to scatter incident light away from the viewer or it can be optically coated to reduce the reflected light to achieve improved viewing. Some times both methods are used (Dearborn Glass Co, 1971). Reduced gloss surfaces are also involved with the reduction in surface glare. The level of increased roughness of the surface affects the user's ability to see details.

Fig. 2 9-point testing of the uniformity of a display, where the black dots denote the testing points.

Uniformity

The uniformity of a display is how consistent an image appears on the screen in terms of luminance, color, etc. For instance, luminance uniformity is defined as the ratio of the smallest luminance on the screen to the largest, which is usually required to be higher than 0.75 for a qualified display (Keller, 1997). To measure the luminance uniformity (or uniformity in terms of other metrics), a 9-point testing is often implemented, which measures nine testing points uniformly distributed on the screen with the aid of certain test charts, as shown in Fig. 2. Sometimes, a similar 16-point testing is also adopted. Also based on the 9-point testing, the chromatic uniformity in 1976 CIE (u' , v') color space can be measured, as given by Eq. (4).

$$\Delta u'v' = \frac{\sum \sqrt{(u'_i - u'_0)^2 + (v'_i - v'_0)^2}}{N} \quad (4)$$

where (u'_0 , v'_0) is the chromaticity coordinate of a reference, such as the central point of the screen or a designated color.

Contrast Ratio

When people talk about contrast they generally mean “contrast ratio.” The contrast ratio of an area on a display is a unitless parameter that is defined as the ratio of the luminance of the brightest color to that of the darkest color (Lee *et al.*, 2008; Yeh and Gu, 2010). Contrast ratio is a general concept that has not been officially standardized across different types of displays and measurement methods. For LCDs or other modern displays, the most widely adopted conceptions are static contrast ratio and dynamic contrast ratio.

Static contrast ratio is the fundamental and inherent characteristic of a display that is the luminosity ratio of the brightest color to the darkest that the display is able to produce simultaneously at any instant of time. Two methods are usually used to measure the static contrast ratio, as (1) native on/off method, which sequentially adopts a full black signal and then a full white signal, and (2) ANSI method, which adopts a checkerboard pattern containing fully black and white colors simultaneously (Pavlovych and Stuerzlinger, 2005). The native on/off contrast ratio is always a little higher than the ANSI one, so commercial products are always characterized by ANSI contrast ratio. In LCDs, certain backlight intrinsically leaks through LC cells even if a black signal is displayed; i.e., LC cells cannot be completely closed, which restricts the contrast ratio of an LCD. Generally, modern LCDs can achieve a native on/off contrast ratio of approximately a thousand to one. Next-generation displays, such as OLED and micro-LED displays (Pavlovych and Stuerzlinger, 2005; Putman, 2016), directly emit light from the screen without backlight; thus the pixels actually produce “no light” for a black signal, and then, the contrast ratio can be way much higher.

Dynamic contrast ratio is the luminosity ratio of the brightest to the darkest color over time, which is usually measured by dynamic on/off method. What is different from the native on/off method is that a mechanical iris or electronic signal processing is allowed to help increase the contrast ratio. Local dimming or some brightness boost technologies that can be found in modern displays can also be utilized (Huang *et al.*, 2011). Obviously, dynamic contrast ratio measured in such a manner is (much) higher than static contrast ratio. Some LCD manufacturers announce that their products can even reach a dynamic contrast ratio of higher than 10,000,000:1. However, since software or circuit based contrast ratio enhancement technologies and measurement conditions have not been standardized, dynamic contrast ratio is usually not compared across different display devices.

Additionally, the effect of ambience on contrast ratio measurement should also be considered sometimes. If the measurement is implemented in a room with reflective walls, light threw out from the display will be reflected back by the walls and then degrade the contrast ratio.

Finally, the variation of contrast ratio with viewing angle also needs to be paid attention. Modern display technologies, such as emissive OLED displays or in-plane switching (IPS) LCDs, can realize quite homogenous contrast ratio over a wide range of viewing angles, while twisted nematic (TN) LCDs have a poorer performance, like that shown in Fig. 3.

Fig. 3 Iso-contrast contours of angular-dependent contrast ratios of a conventional TN LCD (left) and a viewing-angle-enhanced LCD (Hwang *et al.*, 2009). Reproduced from Hwang, S., Min, J., Lee, M.G., *et al.*, 2009. Novel wide viewing liquid crystal display with improved off-axis image quality in a twisted nematic configuration. *Optical Engineering* 48(11). doi: 10.1117/1.3265524.

Ambient Illumination and Reflection

A display for users to see the information is exposed in an ambient illumination, like bright daylight; hence ambient contrast ratio (ACR) that takes reflected ambient light into account is usually used. ACR of a display with an overall reflectivity R can be calculated with Eq. (5) (Singh *et al.*, 2012; Qin *et al.*, 2015). It can be seen that higher ambient luminance contributing both to the numerator and the denominator leads to a lower ACR.

$$ACR = \frac{L_{on} + R \cdot L_{amb}}{L_{off} + R \cdot L_{amb}} \quad (5)$$

where L_{on} , L_{off} , and L_{amb} is luminance of the brightest color, the darkest color, and the ambience.

With the development of flat panel displays, displays are widely used in portable electronic devices. It is a common scenario that a user watches a display in the bright daylight; thus the "specular reflection" (Snell's Law type of reflection) on the front glass of the display will degrade the contrast ratio severely. This reflection is reduced by methods such as anti-glare (AG) and anti-reflecting (AR) surfaces applied to the front surface of a display. Surface roughness is used in AG surfaces to scatter a portion of the specular light away from the viewer. Surface roughness can be achieved through surface abrading, surface plastic coating, surface silicate coating, and surface acid etching to name a few methods. AR surfaces use optical interference techniques to reduce the reflected light to the viewer. In some cases, both methods are applied to a display surface. If an AG coating is used, the image sharpness will be affected by the reduction in specular reflection through the use of surface roughness; thus ambient light reflection and image sharpness should be traded off to acquire the optimum image quality. On the other hand, AR coatings improve glare reduction without scattering and thus give higher resolution capability to the displays but this is usually obtained at a higher price than the AG coating (Chen, 2001).

Moreover, like OLED displays, the ambient light reflection is caused by the metallic electrodes inside the display, hence AG or AR coating on the front surface does not take effect. The most common approach for such an internal reflection is to use a linear polarizer along with a quarter wavelength retarder, so that the ambient light can be absorbed before it exits the display, as shown in Fig. 4 (Singh *et al.*, 2012; Qin *et al.*, 2015). Nevertheless, the use of a polarizer cuts off at least half of the emissive light, and a considerable thickness of the polarizer plus the retarder is not expected in flexible displays. Therefore, some new techniques are under development, such as "black cathode (Xie and Hung, 2004)," microlens array with black matrices (Qin *et al.*, 2015), etc.

Bidirectional Reflectance Distribution Function

An effective tool is bidirectional reflectance distribution function (BRDF), which can describe reflection properties at different viewing angles versus light with different incident angles (Marschner *et al.*, 2000). Fig. 5 and Eq. (6) explains how BRDF works with four variables. Its value equals to the ratio of the reflected radiance in the outgoing direction to the irradiance in the incoming direction. BRDF can comprehensively depict the reflective property of a surface, so that it can be widely utilized in optical

Fig. 4 Elimination of ambient light reflection in a display containing metallic electrodes by using a linear polarizer with a quarter wavelength retarder. The straight and circular arrows demote linearly and circularly polarized light, respectively. The directions of the arrows denote the polarization direction.

Fig. 5 Illustration of the definition of BRDF. θ and Φ denote the direction. The subscripts “i” and “r” denote incoming and reflected light, respectively.

Fig. 6 Angular luminous intensity distribution of a Lambertian surface in a polar coordinate system.

design, computer graphic, computer vision, etc. Common BRDF models include Lambertian, Lommel–Seeliger, Phong etc. (Langovoy and Wübbeler, 2013)

$$BRDF(\theta_i, \Phi_i, \theta_r, \Phi_r) = \frac{L(\theta_r, \Phi_r)}{E(\theta_i, \Phi_i)} \quad (6)$$

where L donates radiance and E donates irradiance.

Lambertian Surface

An ideal diffusive surface that is important in displays obeys Lambert's cosine law, so called Lambertian surface (Warren, 2007). A Lambertian surface reflects light with luminous intensity proportional to cosine of the viewing angle (the angle between the direction of reflected light and the surface normal), whose luminous intensity profile is shown in Fig. 6. More important, its luminance is isotropic regardless the viewing angle, resulting in appearing equally bright to observers in all directions. BRDF of Lambertian surface is a special case that BRDF is a constant of ρ/π where ρ is the albedo.

Viewing Angle and Viewing Cone

Viewing angle is defined as the maximum angle, within which a display can provide acceptable visual performances (luminance, chromaticity, etc.) to the observers (Lee *et al.*, 2008; Yeh and Gu, 2010; Teunissen *et al.*, 2008). A display may perform differently in different directions, hence horizontal and vertical viewing angles are usually used to gauge a display. In fact, the most frequently used viewing angle is defined by the luminance. According to different definitions, the viewing angle in terms of luminance can be defined as the angle where the luminance descends to one half or one third of the on-axis value. To be more comprehensive, a more complicated concept, as viewing zone, is sometimes adopted for a display. Viewing cone is defined as “the range of viewing directions that can satisfactorily be used for the intended task without reduced visual performance” in ISO standards, which is actually the multitude of viewing angles in all viewing directions, leading it to appear in an inverted “cone” with its apex on the display. According to different usage scenarios, different aspects of performances, such as luminance, chromaticity, contrast, can be adopted to define the viewing cone. To conveniently represent a viewing cone, a contour or heat map in a polar coordinate system is usually recommended.

Resolution and Image Sharpness

The resolution of a television, computer monitor, cellphone display etc. is a specification that denotes the distinct pixel amount in each dimension that can be displayed. Usually, resolution with the unit of pixel is expressed in width $\times$ height. For example, 1920×1080 means 1920 pixels in the horizontal direction and 1080 pixels in the vertical direction. For modern displays with a fixed pixel array, such as LCD, digital light processing (DLP) projector, OLED display, etc., the display resolution is directly the number of physical pixels. Some common display resolutions are shown in Table 2. The resolution of a display also refers to the image sharpness of it; that is, the higher resolution, the finer image detail that can be displayed.

Pixels Per Inch

Sometimes, to give not only the total pixel number, but also the pixel density, another parameter associated with display resolution, as pixels per inch (PPI), is also used. By giving PPI, the viewing distance, over which the human eyes cannot distinguish between pixels of a display, can be determined. For instance, a pixel density around 400 PPI is satisfactory for high-end smartphones; virtual-reality (VR) and augmented-reality (AR) devices usually call for a PPI larger than 600; and light field displays even requires a PPI of several thousands. Table 3 shows PPIs of some typical consumer electronic products released these years.

Color Temperature

Color temperature originally comes from ideal black-body radiators that emit light with different hues at different temperatures, and is adopted to evaluate the hue of light sources in Kelvin (K) (Wyszecki and Stiles, 1982). The Planckian locus in Fig. 7 shows the chromaticities of a black-body radiator of different temperatures on CIE 1931 (x, y) chromaticity diagram. Generally speaking, the lower the color temperature is, a white light appears more reddish; the higher the color temperature is, the white is more bluish. For stimuli that do not exactly follow the form of black-body radiators, the concept of correlated color temperature (CCT) is commonly used, which is the temperature of a Planckian radiator whose perceived color most closely resembles that of the given stimulus at the same brightness and under specified viewing conditions. In Fig. 8, chromaticity coordinates having the same CCT are marked with black lines, revealing that different colors may have the same CCT.

Under NTSC, PAL TV norms, a display should reproduce electrically black and white signals with the minimal color saturation at a color temperature of 6500K (The value may differ in some other norms). By considering that it is high-cost to precisely preprogram or calibrate a display's color temperature to be 6500K or other designated values, many consumer products have

Table 2 Some common display resolutions

Standard name	Aspect ratio	Width (pixel)	Height (pixel)
SVGA	4:3	800	600
XGA	4:3	1024	768
WXGA	16:9	1280	720
HD	16:9	1366	768
HD +	16:9	1600	900
UXGA	4:3	1600	1200
FHD	16:9	1920	1080
WQHD	16:9	2560	1440
4K UHD	16:9	3840	2160
8K UHD	16:9	7680	4320

Table 3 PPIs of some typical consumer electronic products released these years

Product	Release year	Diagonal size (inch)	PPI
Smartphones			
Apple iPhone 4	2010	3.5	330
Samsung Galaxy S II	2011	4.3	216
Apple iPhone 6 Plus	2014	5.5	401
Google Nexus 6	2014	6	490
Sony Xperia XZ Premium	2017	5.8	801
Tablets and laptops			
Apple MacBook Air 13"	2010	13.3	128
Microsoft Surface RT	2012	10.6	148
Amazon Kindle Fire HD	2013	7	216
Apple iPad Air	2013	9.7	264
Apple MacBook Pro Retina 15"	2015	15.4	220

**Fig. 7** Planckian locus on the CIE 1931 (x, y) chromaticity diagram that shows chromaticities of black-body radiators corresponding to different temperatures.

deviations from this requirement, and consequently produce some chromatic differences. To meet different personal preferences of color reproduction, some displays also provide a function of color temperature adjustment.

Color Triangle

In an additive color system, the gamut of all the possible combinations of all the primary colors can be plotted in a polygon with vertexes defined by these primaries (Wyszecki and Stiles, 1982; Smith, 1978). For three primaries, it is a triangle, which is simultaneously the chromaticity gamut when the amounts of the primaries are constrained to be nonnegative, as the Maxwell's triangle shown in Fig. 8. In a Maxwell's triangle, corners of the triangle are three primary colors – red (R), green (G), and blue (B), and other colors are represented by distances from each of the three sides of the triangular to a point inside. After the CIE system was developed, color triangles are used along with chromaticity diagrams. Generally, the sum of the three chromaticity values in modern chromaticity diagrams has a fixed value and only two of the three values are depicted, hence color triangles are plotted in a Cartesian coordinate system. Fig. 9 shows color triangles of some typical color gamuts on CIE 1931 (x, y) chromaticity diagram.

Fig. 8 Maxwell's color triangle, in which a color point (the black dot) can be represented by the distances from each of the three sides, as r , g , and b .

Fig. 9 Color triangles of some typical RGB and CMYK (cyan, magenta, yellow, black) color gamuts, where the name of the color gamuts are marked in the figure.

Response Time

Response time of a display is the time for a pixel takes to change status and is usually with the unit of millisecond ([Lee et al., 2008](#); [Tsujiyura, 2017](#)). Generally, the “change” is defined as that a pixel goes from black to white and back to black again, hence response time is the sum of T_r (time rising) and T_f (time falling). Sometimes, grey-to-grey (GTG) response time that represents the time for a pixel takes to change from a grey value to another is also adopted to acquire a better-looking specification. A long response time may create comet-like tails while objects are quickly moving on a display, so called trailer effect or motion blur; therefore, response time is important to fast moving contents such as sports or video games. LCDs, as the most widely used display technology today, have an inherent issue of low response time, because the liquid crystals need some time to twist. Modern LCDs can achieve a response time of several milliseconds. Blue phase mode LCDs can even decrease the response time to about one millisecond ([Ge et al., 2009](#)).

Refresh Rate and Frame Rate

For displays, refresh rate is the number of times in a second that a display hardware updates its buffer, as known as temporal resolution, while frame rate is the number of times in a second that the image source provides an entire frame of new data to a display. Sometimes, the refresh rate may not equal to the frame rate. For example, an LCD operated under a refresh rate of 60 Hz is

provided with 30 frames per second, so that its refresh rate (60 Hz) is unequal to the frame rate (30 Hz). Since pixels of an LCD do not flash from a frame to another, a minimal refresh rate is not required to eliminate the refresh-induced flicker, whereas this is important for CRTs, whose refresh rate usually needs to be higher than 85 Hz to eliminate the flicker. On the other hand, a high refresh rate of LCDs can smooth the motion objects in the image. Generally, a monitor or TV LCD for regular applications has a refresh rate of 60 Hz. Moreover, LCDs dedicated to video games usually have a refresh rate of 120 Hz, or even 180 Hz to match the high frame rate provided by a graphics card. For some special applications, such as field sequential color displays (Huang *et al.*, 2011), the refresh rate needs to be 240 Hz or even higher. For LCDs with a high refresh rate, the pixel response time should be short enough to realize a rapid grey-to-grey conversion; otherwise, the images will be distorted.

Reflective Display Technologies

Han-Ping D Shieh, National Chiao Tung University, Hsinchu, Taiwan

© 2018 Elsevier Inc. All rights reserved.

In addition to transmissive and emissive displays, reflective displays are also widely used in display applications that call for ultra-low power consumption, sunlight readability, flexibility, low cost etc., such as electronic paper (e-paper), digital signages, electronic shelf labels, wearable displays. For instance, e-paper is a typical application, which is predicted to share more than 10% of the traditional printing and publishing market (Wu and Yang, 2001; Luxresearch, 2015). From 2015 to 2020, the overall market of reflective displays will grow by 30 million dollars reportedly (DisplaySearch, 2016). Several mainstream reflective display technologies including electrophoretic, electro-wetting etc., will be introduced in this chapter.

Electrophoretic Display (EPD)

Electrophoretic is an electro-kinetic phenomenon that refers to the motion of dispersed particles in a fluid when an electric field is applied, which was observed in as early as 1807 (Dukhin and Derjaguin, 1974). Based on this phenomenon, electrophoretic displays (EPDs) are developed (Dukhin and Derjaguin, 1974; Comiskey *et al.*, 1998; Kim *et al.*, 2004; Amundson *et al.*, 2001; Inoue *et al.*, 2002; Oh *et al.*, 2009; Lee and Liang, 2003; Liang *et al.*, 2003; Huang *et al.*, 2013; Li *et al.*, 2016). Generally, an EPD contains two electrode layers sandwiching an ink layer where white particles (usually positively charged titanium dioxide) and black particles (usually negatively charged carbon black) are suspended, as shown in Fig. 1(a). By applying an appropriate voltage across the electrode layers, the particles will move under the electrostatic force. When the white particles gather at the top electrode, the ambient light will be diffusely reflected and a white state will be observed. In the opposite case, the black particles are pushed to the top electrode, hence the ambient light is absorbed and a black state is given. To form an image, active matrix driving technology is usually utilized to separately drive a number of regions of the display. In addition to white and black particles with opposite charges, another alternative principle of EPD is to use particles with opposite charges and colors respectively at both sides, as shown in Fig. 1(b). When an electric field is applied, the particles will be rotated and moved by the field stress; hence, the color appearing to the observers changes. For an actual EPD, the driving waveform, which forces the charged particles to move towards or away from the observers, plays an important role in sequentially erasing the original image, activating the particles, and displaying a new image. Therefore, the driving waveform algorithm should be carefully optimized for driving time, grayscale, flicker and ghost.

The most significant advantage of EPD is its power saving feature introduced by the “bistability,” which denotes that a system has two stable equilibrium states. For displays, “bistability” means a display can retain a still image without power consumption in two states (usually black and white). In an EPD, positions of the charged particles are retained when the applied voltage is removed. Consequently, the displayed image can be kept when the power source is removed and the display consumes little power when it shows still images. In contrast, in traditional LCDs, the backlight needs to be lightened and the driving circuit needs to be rapidly refreshed all the time. Next, EPDs use basically the same pigments as the regular ink for printed paper to reflect the ambient light, hence it has the same satisfactory contrast ratio and viewing angle as printed paper, especially in the bright sunlight. Thirdly, the displayed images of EPDs are essentially generated by reflected ambient light, hence the healthily harmful light possibly in transmissive and emissive displays can be prevented. Fourthly, the resolution of EPDs can directly benefit from active matrix driving technology that is fast growing (Amundson *et al.*, 2001). Additionally, all components of an EPD can be made flexible to realize a bendable or even rollable display. Therefore, EPDs are now widely used for e-readers and gain increasing attention for architecture displays, wearable displays, electronic signages etc. However, the response time of EPDs of hundreds of milliseconds somewhat restricts their application for animation or video contents. In addition, due to the difficulty of accurately controlling the charged particles, the bit number of gray-level of an EPD is a little poor in comparison with conventional LCDs. For example, 6-bit gray-level is quite prominent for an EPD while an entry-level LCD can easily achieve 8- or even 10-bit gray-level. This issue of bit number further affects the color rendering capacity. Currently, an active research area of EPD is to enhance the color gamut to expand the application scenarios.

Fig. 1 Basic principle of EPD: (a) using black and white particles with opposite charges; (b) using opposite charges and colors at both sides of a single particle.

Microencapsulated Electrophoretic Display

In an EPD, to solve the issues of lateral drift caused by the gravitation and particle agglomeration caused by the direct contact between the particles and electrodes, the particles suspended in a fluid are enclosed in tiny microcapsules with a scale of dozens of microns, so called microencapsulated EPD (Oh *et al.*, 2009). Microencapsulated EPDs can achieve improved reliability and realize direct coating of microencapsulated electrophoretic materials on the substrate, which leads to potential flexibility. Fig. 2 shows the principle of a monochrome microencapsulated EPD using white and black pigments with opposite charges. The applied voltage pushes the charged white or black pigments to the top electrode to make the display appear white or black to the observers. The voltage applied to each microcapsule can also be bifurcated, then the mixture of white and black particles can realize different gray levels. If color filters are added onto these microcapsules, reflected ambient light passing through the color filters can realize a chromatic microencapsulated EPD (Oh *et al.*, 2009), as shown in Fig. 3.

Microcup[®] Electrophoretic Display

Another practical EPD technology uses microcups to enclose the particles and fluid, so called microcup[®] EPD (Lee and Liang, 2003; Liang *et al.*, 2003; Huang *et al.*, 2013). An example of monochrome microcup[®] EPD with two types of pigment is shown in Fig. 4. The size of a microcup, which can be prepared by a lithographic or embossing process, may vary from 50 to 180 μm in diameter, 12 to 40 μm in height, and 8 to 25 μm in partition width, depending on the application. A unique feature of microcup[®] EPD is that the microcups can be easily imprinted onto a flexible substrate and driving backplane with a mature roll-to-roll (R2R) processing, thus flexible microcup[®] EPDs can be produced at relatively low cost rather than microencapsulated EPDs. Additionally, microcup[®] EPDs can also be made chromatic by using chromatic fluid or a three-pigment-ink system (Oh *et al.*, 2009; Lee and Liang, 2003; Liang *et al.*, 2003; Huang *et al.*, 2013; Li *et al.*, 2016), as shown in Fig. 5. Benefiting from no use of color filters, the reflectivity can be made quite high for a chromatic microcup[®] EPD.

Electro-Wetting Display (EWD)

The electro-wetting phenomenon refers to a modification of the wetting properties of a surface, which is typically hydrophobic, with an applied electric field (Lippmann, 1875). In electro-wetting, two terms including surface tensions and electrostatics are involved to acquire a force equilibrium, as given by Eq. (1).

$$\gamma_{LV}\cos\theta = \gamma_{SV} - \gamma_{SL} + \frac{\epsilon_0\epsilon_r}{2d}V^2 \quad (1)$$

Fig. 2 Principle of a monochrome microencapsulated EPD where (a), (b) and (c) show the cases of white, black and gray visible to the observer, respectively.

Fig. 3 Principle of a chromatic microencapsulated EPD where red (R), green (G) and blue (B) color filters are added.

Fig. 4 Principle of a monochrome microcup[®] EPD where (a), (b) and (c) show the cases of white, black and gray, respectively.

Fig. 5 Principle of a chromatic microcup® EPD: (a) using chromatic fluid and control the position of particles in a microcup to generate colors with different brightness; (b) using a three-pigment-ink system to generate white, black and one more color, which is usually used to enable electronic signages.

Fig. 6 Principle of a typical EWD using chromatic oil and water: (a) colored (blue) pixel; (b) white pixel where part of the electrode is omitted in the lower left corner of each pixel to control the oil motion.

where γ_{LV} , γ_{SV} , γ_{SL} is respectively surface tension of the liquid/vapor, solid/vapor, and solid/liquid interface; θ is the contact angle; ϵ_r is dielectric constant; d is the thickness of the hydrophobic insulator.

Electro-wetting has been utilized for a variety of applications, such as displays, optical filters, fiber optics, adaptive lenses, lab-on-a-chip. Among these applications, electro-wetting display (EWD) is one of the most important, which was firstly proposed in 2003 (Hayes and Feenstra, 2003). Fig. 6 shows the principle of a typical EWD (Hayes and Feenstra, 2003; Feenstra and Hayes, 2009; Hayes et al., 2004; Blankenbach, 2008; Burns et al., 2005; Charipar et al., 2015; You and Steckl, 2010). In a pixel, the non-polarized oil containing chromatic dye is dropped on a hydrophobic electrode with an insulating coating, and enclosed by hydrophilic ribs. The oil and electrode are immersed in a polarized water solution. When no voltage is applied, the oil forms a homogeneous film between the water and the insulating coating to acquire the minimum Gibbs free energy, resulting in a colored pixel, as shown in Fig. 6(a). When a voltage is applied across the hydrophobic insulating coating, an electrostatic force is added to the original force equilibrium. To acquire the minimum Gibbs free energy again, the water is moved into contact with the insulating coating; thus, the oil is pushed aside and the white substrate is exposed to form a white pixel, as shown in Fig. 6(b). For a typical pixel size of about 200 μm , the interfacial tension force is more than 1000 times stronger than the gravitational force, thus the displayed images are stable in all orientations. Moreover, the state of a pixel can be continuously tuned between on and off states by setting a certain balance between the electrostatic and surface tension forces. Consequently, different gray levels can be analogously acquired for an EWD. If pulse width modulation (PWM) is adopted, different gray levels can also be digitally realized. Certainly, black or transparent oils can also be utilized in combination with a substrate of different colors, and the working principle is similar except the pixel color.

The switching time between on and off states of an EWD is typically several milliseconds; hence, an EWD is sufficiently fast to show video contents. Current EWDs can go through over a billion times of switches without a degradation of electro-optical performances, revealing a long working life of EWD for video contents. Moreover, under a low operation voltage of around 20 V, the power consumption of an EWD is just about one third of that of conventional transmissive LCDs, leading to an attractive feature of power saving. Due to the reflection of ambient light via the oil or substrate, reflectivity, contrast ratio, viewing angle, sunlight readability etc. of EWDs is comparable to those of regular printed paper. Finally, since the electro-optical performances of

Fig. 7 Principle of a bistable EWD utilizing droplet movement. E_0 is common electrode, and E_1 , E_2 are structured control electrodes, which are applied opposite waveforms in phase while moving the droplet.

Fig. 8 Principle of a chromatic EWD: (a) adding a color filter onto each pixel containing black oil; (b) stacking three monochrome layers (cyan, magenta and yellow).

an EWD pixel is insensitive to the cell-gap, which is hard to be homogeneous across the screen for a flexible display, the fabrication of flexible EWDs is relatively easy and low-cost (Burns *et al.*, 2005). Furthermore, EWDs and conventional LCDs share around 90% of the production process, leading to a promising prospect of commercialization. However, an EWD utilizing droplet (oil) contracting and relaxing is not bistable, hence it consumes power when still images are shown.

To make EWD adapted for applications that need a bistability, such as e-readers and digital signages, some researchers have realized bistable EWDs (Charipar *et al.*, 2015) by utilizing droplets moving from one position to another, as shown in Fig. 7. Nevertheless, the response time of a bistable EWD is lower than that of a non-bistable one.

EWDs can also be adopted to realize low-cost and power-saving color displays (You and Steckl, 2010). The first approach is simply adding color filters onto each pixel containing black oil to form a chromatic sub-pixel, as shown in Fig. 8(a). As the manufacturing process for traditional LCDs using color filters can be directly utilized here, the cost is considerably low while a higher optical efficiency than that of LCDs can be offered because of no polarizers. The second approach is stacking three monochrome layers that can be separately controlled, as shown in Fig. 8(b). By adjusting the driving voltage of each layer, a desired color can be generated via subtractive color-mixing principle. This triple-layer architecture can directly adopt the processes for single-layer to suppress the cost, in addition to a much higher optical efficiency. Benefiting from the triple-layer structure, the color rendering capacity of such an EWD is much higher than that of other reflective displays. Furthermore, due to the subtractive color-mixing principle, the color gamut and brightness have a win-win relationship for a triple-layer EWD, while a trade-off needs to be endured for a conventional LCD adopting additive colors.

Other Reflective Display Technologies

In addition to EPD and EWD, there are several other reflective display technologies, such as quick response liquid powder display (QR-LPD) (Hattori *et al.*, 2004), cholesteric liquid crystal display (ChLCD) (Tamaoki, 2001), interferometric modulator display (IMOD, trademarked mirasol[®] by Qualcomm) (Bita *et al.*, 2012), memory LCD (Tamaki *et al.*, 2014). Although they have not been widely commercialized, several attractive features can be found in these technologies. Here their principles and features are briefly summarized in Tables 1 and 2.

- (1) QR-LPD[®]: A QR-LPD[®] is based on electrophoresis, where high-fluidity black and white “liquid powders” at nanometer scale are charged and suspended in the air to be driven by two electrodes sandwiching the powders. When a negative voltage is applied to the upper transparent electrode, the black powders with positive charges aggregate on the top, and then bring

Table 1 Principles and features of several reflective display technologies (1)

Technology	QR-LPD	ChLCD
Principle	White state  Black state 	 
Advantages	Fast response (< 1 ms), low temperature driving, wide viewing angle, power saving due to bistability	No use of color filter or polarizer, wide color gamut, power saving due to bistability
Disadvantages	High driving voltage, low contrast ratio	Slow response (~ 300 ms), low resolution, high cost, high driving voltage
Leading companies	Bridgestone	Fujitsu, Fujitsu Xerox, Kent Displays, ITRI

Table 2 Principles and features of several reflective display technologies (2)

Technology	IMOD	Memory LCD
Principle	White state  Black state 	 
Advantages	Fast response (~ 10 μ s), power saving due to bistability, high contrast ratio, high reflectivity ($> 60\%$), high robustness	Low power consumption due to bistability
Disadvantages	Low resolution of gray scale, high cost	Limited resolution and color rendering capacity due to the complication of SRAM circuit integration
Leading companies	Qualcomm	Sharp

about a black appearance, while a positive voltage applied to the upper electrode produces a white appearance in the opposite case. Reflection by the white powders makes a QR-LPD to have a paper-like appearance and wide viewing angle. Due to the high fluidity of the liquid powders induced by their surface morphology and electronic property, response time of

- a QR-LPD is ultra-fast, as shorter than 1 ms. Additionally, the electric field forces between the electrodes and liquid powders give a QR-LPD a bistability feature, resulting in ultra-low power consumption. By optimizing the charge amounts for liquid powders of different colors, a colorful QR-LPD can be realized.
- (2) ChLCD: A cholesteric liquid crystal with chirality caused by a helical structure is contained in a ChLCD. The liquid crystal is arranged in layers with no positional ordering within layers, while director axes of the layers vary periodically, leading to Bragg reflection to the incoming light. When the incident wavelength is between $n_o p$ and $n_e p$, where n_o is the ordinary refractive index, n_e is the extraordinary refractive index, and p is the cholesteric pitch over which the cholesteric liquid crystal molecules fully rotate 360° along their helical, a certain light wavelength is selectively reflected. In this way, it is possible to realize vivid color images without color filters and polarizers. On the other hand, a focal conic domain configuration makes the light pass through and absorbed by an absorption layer beneath to make a dark state. A ChLCD is also bistable (planar state and focal conic state), thus little power is consumed to maintain a still image. To achieve a full-color ChLCD, a stacked-panel technology can be adopted.
 - (3) IMOD: Vivid colors on a butterfly's wings or a peacock's feathers, which are generated by light interference, are imitated. In an IMOD, each pixel is actually a micro-electromechanical system (MEMS) device that contains an air gap sandwiched by a thin-film-coated glass substrate on the top and a reflective conductive membrane at the bottom. The thickness of the air gap at micrometer scale can be tuned by applying a voltage on the top glass substrate and bottom membrane. In this way, a constructive or destructive interference occurs; and then the incoming light with a certain wavelength can be selectively reflected or collapsed. To build a full-color pixel, grids of red, green and blue color subpixels are combined and gray levels are produced by using spatial dithering. An IMOD calls for very little power to maintain either one of its two states to realize a bistable display. Moreover, the interference light from the ambience leads to a great sunlight readability.
 - (4) Memory LCD: Memory LCD, as known as memory-in-pixel (MIP) reflective LCD, adopts reflective electrodes under LC cells and integrates a static random access memory (SRAM) circuit and LC driver into each subpixel (under the reflective electrodes) using conventional TFT technologies. When a still image is displayed, benefiting from the SRAM circuit, only the pixel circuit is driven, leading to no charging current to the data line and a very small amount of charging current to the pixel capacitor. Therefore, a memory LCD is bistable-like and the power consumption of it is ultra-low. Nevertheless, due to the considerable complication of integrating a memory circuit into each subpixel, the resolution of a memory LCD is highly limited. In addition, the bit number of the in-pixel memory is also limited, as only one or two bit; thus, the color rendering capacity is also low in comparison with other reflective display technologies.

Introduction

Optical sensing technology has been widely employed in a variety of biomedical applications due to its noninvasive and nonionizing nature (Mycek and Pogue, 2003). The core components comprising the optical sensor are a light source and a detector. The light source excites a sample with different intensities, wavelengths, time-scales, and coherences of light suited to the biophysical characteristics being investigated. The detector receives the re-emitted light that has interacted with tissues and typically converts a photon signal into an electrical signal to be read by an electronic recording system. Conventional light sources include various types of lasers and lamps to generate photons. Light detecting devices commonly used in tissue optical sensing include photomultiplier tubes (PMTs), silicon photodiodes (PDs), and image sensors such as complementary metal-oxide-semiconductor (CMOS) and charged-couple device (CCD).

Typically, these optical components are bulky, resulting in a large footprint of the final instrument that integrates all the optical and electronic hardware units (Pitts and Mycek, 2001; Lloyd *et al.*, 2010). The large size of these photonic medical devices can limit their mobility, requiring patients to visit the clinical location of the device. Further, if an optical fiber is employed to deliver light to tissue, disadvantages could include inefficient coupling, limited bend radius, the possibility of breakage and low spatial information.

During the past couple of decades, advances in techniques for handling new semiconductive materials, micro-/nano-fabrication technologies, and tiny electronics with high computing power have revolutionized the engineering of miniaturized optoelectronic sensors. Compared to fiber-based optical sensors, miniaturized optoelectronic sensors offer substantial benefits. Dramatic reductions in size, cost and power consumption have great potential to make light-based sensing more ubiquitous than ever. Beyond implementing point-of-care diagnostics, these sensors can be wearable, enabling continuous, noninvasive and object monitoring anytime and anywhere. The end terminal of this “fiber-less” sensor is an electrical signal that can be wirelessly transmitted, thereby providing subject’s mobility with tremendous flexibility. Miniaturized sensors also enable optical inter-rogation in human organs where traditional fiber-optic-based approaches fulfill very limited tasks.

In this article, we will review the basic construction of miniaturized sensors, major optoelectronic components and assembly techniques, data processing algorithms and their tissue diagnostics applications.

Optoelectronic Sensing System

Fig. 1 illustrates a block diagram of the miniaturized optoelectronic sensing system. The system can be divided into two parts. One is a sensing unit comprised of optoelectronic modules that send and receive photons to and from biological tissues, in which the conversion process occurs between photonic and electrical signal. The other is a control electronics unit that controls the excitation and reading sequence via an electrical signal sent or received by the sensing unit. Depending on the sensor design and application, only the sensing unit can be constructed in a miniaturized form (under a few millimeter scale), communicating with relatively large control electronics located on a remote site via physical wiring. The detailed technique for sensor unit fabrication is discussed in a later section. Alternatively, the two parts can be integrated in one platform utilizing the CMOS microfabrication technique of electrical circuitry or direct use of minimal electronic bare chips. This integrated optoelectronic sensor can independently work as a separate sensor node.

The sensing unit consists of an optoelectronics source, an optoelectronics detector and micro-optic components such as micro-lenses or color filters. The optoelectronic source is powered to emit light at a predetermined intensity given voltage and current supplied by the control electronics. The use of a micro-lens on the source’s emission aperture adjusts the divergence of the beam. The incident photon interacts with a variety of micro-organisms, and its properties are altered (e.g., intensity – attenuated by natural chromophores such as hemoglobin, wavelength – fluorescence molecules) as it propagates through the tissue. The optoelectronic detector captures remitted light exiting the tissues, which contains information about tissue morphology, physiology or metabolism. Before light enters the detector, a micro-lens can determine an acceptance angle, and a micro-fabricated filter selects the wavelength range. We will not discuss the types and technologies of the micro-lens and optical filters as they are beyond the scope of this article.

Optical contrasts used by optoelectronic sensors are classified into two groups: exogenous and endogenous. Exogenous agents such as fluorescence protein, oxygen-sensitive dye and gold nanoparticle can be inserted or labeled with a specific target molecule to enhance the signal. For label-free sensing, the optoelectronic sensor can employ endogenous contrasts. In reflectance mode, scattering from micro-organelles such as nuclei and mitochondria, and absorption by natural chromophores such oxy- and deoxy-

Fig. 1 Schematic diagram of an optoelectronic sensor for tissue diagnostics. ADC: analog-to-digital converter.

hemoglobin, bilirubin and beta-carotene can alter the detected reflectance. In fluorescence mode, metabolic cofactors such as nicotinamide adenine dinucleotide (phosphate) (NAD(P)H) and flavin adenine dinucleotide (FAD) or extracellular matrix (e.g., collagen) can serve as intrinsic fluorescence sources (Lloyd *et al.*, 2013).

In general, there are three different types of techniques in optical sensing relating to domain: continuous, frequency domain and time domain. Most current miniaturized optoelectronic sensors are based on continuous sensing (only light intensity measurements) due to the technical complexity in miniaturization of necessary components for frequency- and time-domain sensing. Thus, we premise the continuous sensing technique when we discuss design, data analysis and applications of the optoelectronic sensors.

Designing optoelectronic sensors for tissue diagnostics considers numerous engineering factors including electrical, optical, thermal, and mechanical aspects. The signal-to-noise ratio (SNR) is one of the most important metrics to achieve the basic function of the designed sensor. SNR is defined as

$$\text{SNR(dB)} = 20 \log \frac{\mu}{\sigma}. \quad (1)$$

Here, μ is the mean and σ is the standard deviation of the repetitive measurements on a sample. Typically, tissue-simulating phantoms mimicking optical properties of targeted biological tissues are employed to obtain the SNR of the sensor. SNR is determined by various elements such as source intensity, detector sensitivity, source–detection separation and electronics design (source driver and signal conditioning circuit). The maximum of excitation intensity is ideally desirable for highest SNR, but it needs to be carefully selected to prevent thermal damage of interrogated tissues. In applications requiring sensor implantation or direct contact with human tissues, a biocompatible encapsulation of the sensor is indispensable to avoid tissue compromise via physical and chemical isolation. At the same time, this encapsulation protects the sensor against the watery environment of tissues.

Thermal stability is another critical factor to be considered in optoelectronic sensor design for two main reasons. Because the operation of the optoelectronic components is highly sensitive to temperature, the optical performance of the designed sensor could vary without careful design of heat sink or transfer. In a miniaturized form, a heat sink might not be a feasible option. Ideal design would have negligible or stabilized temperature increase from heat dissipation of source operation, even during long-term use. Optical and thermal simulation tools are useful for evaluating the initial feasibility of the design.

Optoelectronic Components

Laser diode (LD)

A laser diode (LD), also known as an injection diode laser, is a forward-biased semiconductor diode that emits coherent light when electrons and holes are stimulated by an electrical current into the p–n junction (Fig. 2(a)). LDs consist of two stacked layers of

Fig. 2 Illustration of basic structure of (a) laser diode (LD), (b) vertical-cavity surface-emitting laser (VCSEL), and (c) light-emitting diode (LED).

semiconductors as the optical gain medium. The top layer is a p-doped semiconductor, and the bottom layer is an n-doped semiconductor. The layer in between the two semiconductors is the p–n junction, known as the intrinsic region. The intrinsic region is the resonant optical cavity of the laser. When a current is passed through the semiconductors, electrons from the n-type semiconductor and holes from the p-type semiconductor flow into the intrinsic region. Recombination of an electron and a hole releases energy in the form of a photon of light. This photon remains in the intrinsic region and stimulates further release of electrons and holes. The newly formed photons will then be in the same phase, direction and polarization, thereby producing coherent light. Light emerges from one end of the diode and diffracts but can be formed into a straight beam with the use of a collimating lens. Because laser beams are concentrated to a small point, LDs are useful for targeted medical applications that require greater penetration.

Vertical-cavity surface-emitting laser (VCSEL)

A vertical-cavity surface-emitting laser (VCSEL) is a forward-biased semiconductor diode that emits light perpendicular to the laser's top surface as compared to a conventional edge-emitting laser that emits light in the parallel direction (**Fig. 2(b)**). A VCSEL consists of three main layers: the upper p-type distributed Bragg reflector (DBR), the active region with quantum wells, and the lower n-type DBR. The two DBR layers are highly reflective mirrors with a reflectivity of 99.5–99.9%. Photons formed in the active region oscillate between the two DBR layers until they escape as coherent light perpendicularly from the top of the laser. The perpendicular light beam enables three times as many VCSELs to be produced from the same size wafer as compared to edge-emitting lasers. The perpendicular beam also allows VCSELs to be incorporated into two-dimensional arrays to maximize output power and device reliability. Other advantages of VCSELs over edge-emitting lasers include easy coupling with optical fibers due to circular beams, less power consumption, greater quality control during production, and lower production costs.

Light emitting diode (LED)

A light-emitting diode (LED) is a forward-biased semiconductor diode that produces incoherent light. An LED includes a p–n junction where electrons and holes generated from an electric current are recombined (**Fig. 2(c)**). Energy is released as light and heat. The mechanism of light generation is similar to LDs; however, LEDs do not have stimulated emission or coherent light emission. Because LEDs distribute their power incoherently, they are useful for treatment of larger areas of shallow depth. Low power consumption and heat generation associated with LEDs result in improved device efficiency. LEDs are composed of inorganic semiconductors, commonly gallium arsenide phosphide, with long life times. Failure occurs as a gradual, rather than abrupt, decrease in brightness. The durability, compact size, and low production costs of LEDs make them well suited for medical applications. Unlike LDs that emit a coherent light with a narrow bandwidth (~ 1 nm) in a small divergence angle, LEDs emit an incoherent light with a broader bandwidth (typically 25–50 nm) in a larger divergence angle. LEDs come in smaller packages and have more flexibility in available wavelengths than LDs.

Silicone photodiode

A photodiode (PD) is an optical signal receiver. PDs function as semiconductor diodes that detect light with the use of a p–n junction. Incident light is focused onto the junction of the PD. As light enters the charge-depleted region between the p-type and n-type semiconductors and strikes an atom within the crystal structure of the PD, electron–hole pairs are generated. The built-in electric field of the charge-depleted region causes the electrons to drift toward the cathode and the holes to drift toward the anode, creating a photocurrent. The greater the intensity of incident light, the more electron–hole pairs are created. Thus, the generated photocurrent is dependent on light intensity. The total current of a PD includes dark currents, which must be accounted for in calibration. There are different modes of PD operation: the photovoltaic mode, the photoconductive mode, and avalanche PDs. The photoconductive mode creates voltage by restricting the photocurrent flow. In the photoconductive mode, the PD is reverse biased, which increases the width of the charge-depleted region. This width increase decreases the capacitance of the p–n junction, reduces the response time of the PD and increases the linearity of light intensity measurements. However, the photoconductive mode also increases the amount of dark current and noise. Avalanche PDs are highly reverse biased, multiplying the current, and increasing the response of the PD.

Silicone photomultiplier (SiPM)

A silicon photomultiplier (SiPM) is an avalanche PD array joined together on a silicon substrate. Silicon can detect light in the wavelength range 350–800 nm. The array is composed of PD and quenching resistor microcells arranged in parallel. SiPMs have single-photon sensitivity because each individual microcell can detect an incident photon. When a photon is detected, the microcell avalanches as the silicon becomes conductive and amplifies the current (Geiger discharge process). The quenching resistors then stop the avalanche, and the microcells are reset to detect another photon. The released current from all of the microcells can be measured to detect the intensity of light. Therefore, the number of microcells activated is proportional to the amount of incident light. SiPMs are advantageous due to their sensitivity, low operating voltage, and high timing performance. Because of their single photon sensitivity, SiPMs are useful in low-light applications. Currently, SiPMs are being considered for use in positron emission tomography and single-photon emission computed tomography.

Organic LED and PD (OLED and OPD)

Organic LEDs and PDs are composed of organic semiconductors and polymers. Organic polymers allow for greater flexibility and transparent displays. OLEDs and OPDs have several advantages over inorganic LEDs and PDs. Inorganic-based optoelectronics are difficult to scale for large-area production. Organic optoelectronics, however, can be manufactured with flexible substrates and with solution processing, resulting in cheaper and larger volume production. Inorganic components also tend to be more rigid and bulkier. Flexible organic polymers allow organic parts to be used in a wider variety of medical applications. The flexibility of OLEDs and OPDs and their large scalability also introduce the potential for low-cost, disposable medical sensors (Lochner *et al.*, 2014).

Assembly Techniques

Small footprint components soldered on conventional print circuit board (PCB)

The most basic method of constructing an optoelectronic sensor is assembling commercially available packaged components onto a conventional printed circuit board (PCB). Most optoelectronic-based medical devices that have become a standard of care in clinics fall into this category in a hand-held form, allowing for point-of-care diagnostics. The pulse oximeter is the most successful device. The bilirubinometer, which screens for neonatal jaundice by measuring subcutaneous serum bilirubin concentration, is another good example. Their operating principles will be discussed in detail later in the application section. The smallest size of packaged LEDs and PDs currently available is in the range of ~ 1 mm. These components can be manually or automatically soldered onto the PCB, but are not feasible for applications requiring further miniaturization.

Die-level chip assembled on fabricated board with die-attached material

An alternative to using packaged optoelectronic components is assembling unpackaged die-level chips onto micro-fabricated circuit boards for the applications smaller than 1 mm (Fig. 3(a)). The direct soldering of chips is not feasible due to densely patterned interconnections (a few tens of micrometers between patterned lines) or no solder contact metal on the chips. For chips without solder metals on their anode/cathode electrode, a special metal alloy needs to be patterned in the process of fabricating the board. One bonding option utilizes a eutectic alloy like indium–gold (In–Au), which means the melting temperature of the alloy is lower than that of each metal. One advantage of eutectic bonding, in terms of assembly, is that the eutectic-bonded components are not re-melted by another heat process when even higher temperatures are applied (Fig. 4(a)). For the top electrode, wire-bonding is required to make a connection to the bottom interconnections. Some LED manufacturers supply directly attached LED chips of which cathode and anode are on the same side as solder metals. A simple reflow process bonds both electrodes, thus requiring no wire-bonding of the top electrode. Temperature profiles in each heating process need to be carefully controlled because non-optimized processing of temperatures can deteriorate the performance of the optoelectronic components as shown in Fig. 4(b). Even a bare die of an electronic chip can be directly attached to the flexible substrate board (Kim *et al.*, 2017).

Monolithic fabrication of integrated sensor

Maximum miniaturization of a sensor is achieved by monolithically fabricating an integrated sensor (O'Sullivan *et al.*, 2010). The source and detector are fabricated together using fabrication process flow and patterned by photolithography techniques from a single wafer (Fig. 3(b)). The VCSEL is a suitable semiconductor light source for this type of the integrated sensors because it emits light upward with higher intensity and requires simpler fabrication design compared to LED. The fabrication order requires careful consideration since the performance of each source and detector can be critically affected. For high-quality VCSEL lasing, the VCSEL layer needs to be grown before the PD. One advantage of monolithic fabrication is that source–detector separation can be sophisticatedly determined on the order of 100 μm . For a very short distance, the additional structure blocking a direct light pipelining from source to detector is necessary. An interference filter or absorbing-based filter can be used as a blocker and deposition techniques are compatible with the general semiconductor fabrication process of source/detector.

Data Processing Algorithm for Optoelectronic Sensor

Using physical principles on light–tissue interaction, there are various analysis algorithms depending on specific applications. This section will discuss two methods for analyzing diffuse reflectance: (1) the ratiometric method to measure a simple reflectance ratio

Fig. 3 (a) Die-level chips assembled on the fabricated micro-printed circuit board patterned with solder materials for a needle-compatible optoelectronic sensor assessing reflectance ratios. (b) Monolithically integrated fluorescence sensor. From O'Sullivan, T., Munro, E.A., Parashurama, N., *et al.*, 2010. Implantable semiconductor biosensor for continuous in vivo sensing of far-red fluorescent molecules. *Optics Express* 18, 12513–12525.

Fig. 4 (a) Forward voltage–forward current characteristics of the eutectic-bonded LED before and after the following heat process for 2nd LED bonding. (b) Forward voltage–forward current characteristics of the bonded die-level LEDs with different temperatures.

between two discrete wavelengths (one is a contrast and the other is a reference), and (2) the quasi-spectral method that uses multiple wavelengths to mimic a continuous spectrum.

Ratiometric analysis

Intensity-based sensing at single wavelength would be the simplest way to analyze diffuse reflectance but requires a rigorous calibration process to address intensity-induced distortions of such varying source intensity. The ratiometric method avoids this process by using one measurement as reference reflectance intensity. Calculation of the ratio in regard to the reference accounts for measurement errors. For example, in human pancreatic tissue assessment, the reflectance ratio, $R_{470 \text{ nm}}/R_{650 \text{ nm}}$ is suitable to distinguish malignant tissues (adenocarcinoma) from non-malignant tissues, including normal tissues and chronic pancreatitis. In a previous optical study on freshly excised human pancreatic tissues, the reflectance intensities at 450–470 nm differed significantly among these tissue types. This was attributed to different scattering properties depending on nuclei size, refractive index, and collagen contents. On the other hand, the reflectance intensities at 630–650 nm in three tissue types were very close, which served as a reference (Chandra *et al.*, 2007).

Fig. 5 Wavelength-dependent molar extinction coefficients of oxy- (HbO_2) and deoxy- (Hb) hemoglobin. Inset shows isosbestic points.

More generally, employing different wavelengths related to hemoglobin absorption has potential to assess total hemoglobin (Hb) concentration and tissue oxygenation (Hu *et al.*, 2013). Previous studies demonstrated that the ratiometric analysis based on isosbestic and non-isosbestic points has the capability to estimate tissue hemoglobin concentration and oxygenation. Isosbestic points have the same molar extinction for oxyhemoglobin and deoxyhemoglobin wavelengths, for example, 500, 529, 545, 570 and 584 nm (Fig. 5). Non-isosbestic points are the wavelengths showing the biggest difference in absorbance between oxy- and deoxy-hemoglobin, for example, 516, 539, 560, 577 and 593 nm. However, this study employed a full reflectance spectrum acquired by a fiber-based diffuse reflectance spectroscopy. For the optoelectronic sensors, two LEDs with wavelengths as close to isosbestic and non-isosbestic wavelengths as possible can be selected to enable rapid estimation of blood parameters. Rapid and non-invasive assessment of Hb concentration and oxygenation will have many clinical applications, including cancer detection, anemia detection, perfusion monitoring, etc. The main advantage of the ratiometric analysis is the rapid processing time that potentially enables real-time monitoring.

Quasi-spectral analysis

Unlike conventional optical spectroscopy that takes advantage of a continuous spectrum for evaluating tissues, the number of wavelengths available to optoelectronic sensors is limited due to technical difficulties in manufacturing a miniaturized light-dispersing component. However, multiple monochromatic sources with different wavelengths associated with one detector or, alternatively, a broadband source coupled with multispectral bandpass filter installed onto the detector, make the quasi-spectral analysis feasible. Even with a limited number of wavelengths, traditionally employed analysis algorithms utilizing a full spectrum can be applied to extract biophysically relevant parameters or optical properties directly from sensor measurements.

Analytical models have been employed to analyze diffuse reflectance and fluorescence spectrum obtained from human biological tissues (Wilson and Mycek, 2011). The mathematical equation is based on fundamental principles for light scattering and absorption at a given fiber optics probe geometry (Wilson *et al.*, 2010). A reflectance spectrum is calculated from many input variables including nuclei size and refractive index (Lee *et al.*, 2014). By fitting this mathematical model to the obtained reflectance spectrum, the best parameters generating the least error between the model and the experiment are extracted. The original model uses a wide range of wavelengths in the reflectance spectrum from 400 to 750 nm with 2 nm step for a total of 176 wavelengths. However, using only four discrete wavelengths (460, 520, 560, and 630 nm) can also produce results comparable to the model with 176 wavelengths. The reconstructed model fits from two models applied to the same spectrum obtained from human pancreatic tissues are comparable (Fig. 6(a)). The extracted parameters (scattering amplitude) are also similar in each pancreatic tissue type (Fig. 6(b)).

This preliminary comparison demonstrates the possibility of quasi-spectral sensing using the optoelectronic microprobe for noninvasive assessment of biophysically relevant parameters.

Applications

Clinical standard of care

The pulse oximeter is the most representative optoelectronic sensing device and has become a standard of care in clinics. Arterial oxygen saturation (SpO_2) and pulse rate are noninvasively measured (Chan *et al.*, 2013). Consisting of a small LED and PD, the

Fig. 6 (a) Reconstructed spectra by fitting procedure using 176 and 4 wavelengths on the measured spectrum. (b) Comparison of the extracted parameters (scattering amplitude) per different tissue types by inversion algorithm using 176 vs. 4 wavelengths.

Fig. 7 Relative volume of the non-pulsatile (DC) and pulsatile (AC) tissue compartment during a cardiac cycle.

device can be placed on the tip of a patient's finger or ear lobe, allowing for continuous monitoring. Pulse oximetry takes advantage of red and near-infrared (IR) light that can penetrate tissue and be absorbed by hemoglobin. A red LED-emitting light at 660 nm and a near-IR LED with a wavelength of 940 nm are placed on one side of the device. As the light is transmitted through tissue, oxygenated hemoglobin absorbs IR light more than red light, and deoxygenated hemoglobin absorbs red light more than IR light. A PD located on the opposite side of the tissue detects transmitted light. The ratio of transmitted red and IR light is used to determine oxygen saturation of hemoglobin. Pulse rate can also be measured by the transmitted light. A consistent amount of light is absorbed by the tissue and steady venous flow, resulting in a direct current (DC) component of the signal. Pulsatile arterial blood flow creates an alternating current (AC) signal (Fig. 7). The modulation ratio (R) is calculated by

$$\text{Modulation Ratio } (R) = \frac{A_{\text{red-AC}}/A_{\text{red-DC}}}{A_{\text{IR-AC}}/A_{\text{IR-DC}}} \quad (2)$$

where A is the absorbance. This R is typically inversely proportional to SpO_2 and determines absolute SpO_2 values based on a calibration curve empirically obtained from controlled measurements.

The bilirubinometer is another exemplary device that is routinely used to screen neonatal jaundice in preterm infants. Jaundice is monitored by serum bilirubin levels, typically requiring neonates to endure multiple painful blood drawings. However, because cutaneous bilirubin levels are highly correlated with serum levels, transcutaneous bilirubinometers provide a noninvasive method of determining serum bilirubin levels by measuring the yellowness of the skin. Measurements are made using diffuse reflectance spectroscopy. Placing the device on the neonate's forehead or upper sternum activates a pressure-sensitive probe. A light-generating tube transmits light through subcutaneous tissue. Fiber-optic filaments send resultant scattered light to a spectrophotometric module. Light is then split into different spectra between 460 and 540 nm (different devices vary on the number of wavelengths). The absorbance at different wavelengths is compared to known absorption coefficients for all skin chromophores. The amount of yellowness in the skin is calculated as an indirect measurement of bilirubin values.

Cancer diagnostics

Not many optoelectronic sensors have been introduced to investigate human cancerous tissues because there is not a significant need for miniaturization in clinical diagnostics of human cancers. Over the last three decades, optical spectroscopy has demonstrated its potential for noninvasive detection of cancer in various human organs with a sub-cellular level sensitivity evaluating morphological, physiological biochemical changes upon tumor progression. However, only a few attempts to build optical sensing systems with optoelectronic components for either source or detector have been reported. Most of them were to implement sensor arrays for breast cancer imaging. Recently, the needs for miniaturized sensors have emerged to be compatible with an endoscopic channel (2–5 mm) or even with a hollow needle (< 1 mm) targeting some solid tumors such as pancreas, liver, and lung that are accessible only via a hollow needle. Some studies have delivered a fiber optics through this hollow-needle channel to optically interrogate lung and pancreas. However, the miniaturized optoelectronic sensor fitting in this needle could allow for arrangement of multiple source–detector units through a side-view window, which would increase an optical sampling volume (Lee *et al.*, 2017).

Brain research

Since first demonstrated in 1993, functional near-infrared spectroscopy (fNIRS) has been increasingly employed to noninvasively investigate human brain activity by assessing changes in oxygen consumption. Using a deep penetration depth (a few millimeters) of near infrared light, fNIRS is capable of quantifying changes of oxy- and deoxy-hemoglobin concentration in specific brain regions upon external stimulations. The design with multiple pairs of source–detector covers a large area of human brain implementing 2D topological imaging or 3D tomographic imaging that can localize brain activity (Wilson *et al.*, 2016). However, this multichannel system inevitably involves heavy and cumbersome fiber bundles tethered to a remote control system. Most commercial systems use fiber bundles (Fig. 8(a)). The recent wireless fNIRS system based on a miniaturized optoelectronic source–detector pair and signal processing unit has been developed to enable evaluation of brain activity on subjects in a more natural environment (Fig. 8(b) and (c)) (Piper *et al.*, 2014).

Technical advances in optoelectronics/electronics have also opened a new era in functional neuroimaging of animals. Most current optical imaging systems are built with bulky optics and electronic hardware, requiring animals to be restrained and anesthetized, limiting types of experiments and affecting the baseline measurements. In contrast, a miniaturized head-mount optical imaging system enables awake and un-anesthetized animals to be freely moving. Current systems are capable of one photon and two photon imaging using external contrast agents and cerebral blood flow and optical intrinsic imaging via endogenous contrast (Yu *et al.*, 2015).

Summary

Recent technical advances in micro/nano-fabrication techniques, new materials and optoelectronic technologies have enabled fabrication of novel miniaturized optical sensors for in situ tissue diagnostics. In this article, we have discussed the basic construction of the sensors, core optoelectronic source and detector components, sensor fabrication techniques, data processing algorithms, and their clinical applications. The constant innovation in relevant technologies will accelerate development of these miniaturized optical sensors, which will ultimately lead to a paradigm shift in tissue optical diagnostics through noninvasive, objective, wearable, and wireless sensing.

Nomenclature

$\vec{r}$ Vector location of a point of interest in space
 τ Correlation time
 $\Phi(\vec{r})$ Photon fluence rate
 μ_a Absorption coefficient of medium

μ_s Scattering coefficient of medium
 D Optical diffusion coefficient of medium
 $S(\vec{r})$ Input source term
 g Anisotropy coefficient for single scattering of medium

Glossary

Absorption coefficient A wavelength-dependent medium property characterizing the probability of photon absorption in the medium.

Anisotropy coefficient A wavelength-dependent medium property characterizing the mean cosine of the angle between the directions of photon incidence and scattering in the medium.

Coherence The correlation between two (electromagnetic) waves either at different points in space (spatial coherence) or at two different points in time (temporal coherence).

Photon fluence rate The number of photons passing through a specified area per unit of time.

Photon radiance The net photon power passing through a specified area, along a specified direction, per unit of time.

Scattering coefficient A wavelength-dependent medium property characterizing the probability of photon scattering in the medium.

Speckle Small “spots” of bright and dark spots formed when a coherent source is incident on any surface due to constructive and destructive interference at the detector plane.

Temporal autocorrelation function The correlation of a time-dependent function, with itself across the full time-period measured of the original function.

Turbid medium Any medium appears “cloudy” or “murky” due multiple light scattering.

Introduction

Optical spectroscopic methods and techniques have been used for sensing of turbid media such as biological tissues and is an active area of research in the biomedical sciences. The basic prescription in most applications of these methods is to non-invasively derive optical properties of media using experimental measurements in combination with mathematical modeling and analysis to yield quantitative analogues of physiological markers related to human health and disease. Clinical applications over the last two decades have reported using optical spectroscopy for several applications including detection (including surgical margin identifications) of cancer, detection of atherosclerotic plaques, monitoring of burns, wounds and their healing, measuring cerebral functions, and imaging of retinal and dental health.

Optical techniques used for biosensing may be classified as two broad categories – static or dynamic – depending on whether the experimental techniques and methods used are inherently time-integrated, or time-resolved. A large fraction of optical methods that are used to characterize tissue optical properties including diffuse optical spectroscopy and tomography fall under the realm of static techniques – wherein one or more light sources are used to illuminate a medium of interest and a set of measurements (usually at several spatial locations) which are translated to produce a static spatial map of optical properties. It is to be noted that repeated measurements of such static optical techniques as defined here may still be used to study tissue (or biological) dynamics, at time-scales of the acquisition rates of the measurements. Dynamic optical spectroscopic techniques on the other hand make a set of measurements (again at one or more spatial locations) by measuring changes or fluctuations in light intensities (or a shift in the frequency spectrum) across several decades in time and seek to relate these fluctuations to a dynamical varying physical quantity such as motion of particles in the medium.

This article describes a dynamic optical technique – diffuse correlation spectroscopy (DCS) – which combines the theoretical formalism of incoherent photon propagation in a strongly scattering medium, to model experimental measurements of dynamic speckle intensity fluctuations (correlations) measured from the same medium. In DCS, measured speckle intensity fluctuations from an incident monochromatic source is used to compute temporal intensity autocorrelations which in turn are used to extract information about movement of scatterers within the volume of tissue probed by the diffuse optical waves transporting the incident light field to the detector. A closely related optical technique to DCS is Laser Doppler flowmetry which detects the scattered, frequency-shifted spectrum of a monochromatic (coherent) light source after passing through a scattering medium containing moving scatterers. Although these two techniques are closely connected analytically and theoretically as Fourier

transforms of each other, their experimental implementations and analysis are quite distinct. This article will only focus on the description, analysis and applications of DCS for tissue sensing.

Historical Overview and Background

When coherent light is scattered by a material, temporal measurements of the scattered field intensity exhibits fluctuations. Theoretical calculations of such fluctuations of light intensity when scattered by molecules (or other particles) have been studied since beginning of 20th century and include contributions from Einstein, Raleigh, Smoluchowski, and Debye. With the invention of the laser and fast detector-electronics, dynamic light scattering (DLS) became an accessible experimental technique to measure and study a wide variety of dynamic phenomena in complex media such as molecular rotation or diffusion in complex fluids, colloidal particle compositions and biological systems. Historically, DLS theory was developed first for weakly scattering systems (single scattering limit). However, experimentally, the methods of DLS are as applicable to multiply scattering systems as they were to weakly scattering media. DLS was soon applied to study of particle dynamics in various multiply scattering materials and the theoretical modeling of such experimental measurements came to be called diffusing wave spectroscopy (DWS). Experimentally, DCS uses the same experimental theme that is employed in DLS (or DWS) – but instead provides an elegant theoretical encapsulation to analyze the experimental measurements using the now well-established framework of diffusive optical transport in turbid media as sketched in Fig. 1.

Experimentally, all of these techniques employ a long-coherence length laser to illuminate the sample of interest and collect the scattered light intensity from a small volume. Fluctuations in the measured intensity incident on a photodetector and photon-counting system, $I(\vec{r}, t)$ can be obtained. The experimentally calculated intensity unnormalized and normalized correlation functions of these fluctuations are denoted respectively using their standard notations as:

$$G_2(\vec{r}, \tau) = \langle I(\vec{r}, 0) \cdot I(\vec{r}, \tau) \rangle = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T I(\vec{r}, t) I(\vec{r}, t + \tau) dt \quad (1)$$

$$g_2(\vec{r}, \tau) = \frac{\langle I(\vec{r}, 0) \cdot I(\vec{r}, \tau) \rangle}{\langle I(\vec{r}, 0) \rangle^2} \quad (2)$$

The integral in Eq. (1) defines the temporal correlation function of $G_2(r, \tau)$ for an infinitely long time-signal $I(\vec{r}, t)$ while the angular brackets indicate ensemble averages. Although it is usually assumed that the system under observation is ergodic and thus ensemble averages are time averages this may not always be true – we discuss this in the section under Experimental Considerations below. In practice, the temporal correlation is usually calculated using a correlator board (or computer) to numerically evaluate the integral in Eq. (1). The smaller dt is, the more accurately measurements can be expected to match theoretical predictions, with the longest possible correlation time being the total duration of continuous data acquisition. Photodetectors with sampling rates in the 10–100 MHz range are typically used to collect DCS data for 1–10 s for in vivo tissue sensing.

Theoretically, the (detected) intensity is related to the scattered complex electric field from a monochromatic coherent source as $I(\vec{r}, t) = E(\vec{r}, t)E^*(\vec{r}, t) = |E(\vec{r}, t)|^2$ and the corresponding correlations of the detected unnormalized and normalized electric fields are defined as per convention by:

$$G_1(\vec{r}, \tau) = \langle E(\vec{r}, 0)E^*(\vec{r}, \tau) \rangle \quad (3)$$

$$g_1(\vec{r}, \tau) = \frac{\langle E(\vec{r}, 0)E^*(\vec{r}, \tau) \rangle}{\langle E(\vec{r}, 0) \rangle} \quad (4)$$

From the above definitions some properties of the field correlation functions can be computed. $G_1(\vec{r}, 0) = \langle |E(\vec{r}, t)|^2 \rangle = \langle I(\vec{r}, 0) \rangle$, giving $g_1(\vec{r}, 0) = 1$. Also, for long correlation times $G_1(\vec{r}, \tau) = \langle E(\vec{r}, t) \rangle^2 = 0$, giving $g_1(\vec{r}, \tau) = 0$. Given that it is the field fluctuations that give rise to the measured intensity fluctuations, theoretical methods are

Fig. 1 Schematic representation of the DCS setup and its components. The illumination is provided by a laser source coupled to the sample using fiber optical probes. The detected signal is measured using a photodetector (PD) that can provide continuous (temporal) measurements. The monitored intensity fluctuations are recorded using a correlator device to compute the normalized intensity correlation g_2 .

used to generate models that predict behavior of $G_1(\vec{r}, \tau)$ and $g_1(\vec{r}, \tau)$. If the temporal fluctuations in $E(\vec{r}, t)$ are random and assumed to arise due to uncorrelated motions of several randomly (diffusing or moving) particles, then these fluctuations in $E(\vec{r}, t)$ will be normally distributed. Under this condition, $G_1(\vec{r}, \tau)$ and $G_2(\vec{r}, \tau)$ (and their normalized counterparts) are theoretically related through the Siegert relations:

$$G_2(\vec{r}, \tau) = \langle I(\vec{r}, 0) \rangle^2 + |G_1(\vec{r}, \tau)|^2 \quad (5)$$

$$g_2(\vec{r}, \tau) = 1 + |g_1(\vec{r}, \tau)|^2 \quad (6)$$

In DCS the functional form for $G_1(\vec{r}, \tau)$ is hypothesized to follow the same diffusion transport equation governing photon propagation in a multiply scattering medium, while $g_1(\vec{r}, \tau)$ is modeled using the random, independent single scattering model using the formalism of DLS.

Diffusive Photon Correlation Transport

Photon propagation in a turbid medium can be accurately modeled as a random walk of neutral particles in the medium using optical transport coefficients of the medium – typically specified as absorption, scattering and anisotropy. The radiative transport equation provides a theoretical analog for describing propagation of photon radiance within such media. The mathematical form of the transport equation prevents its use practice since it remains intractable for appropriately modeling experimental (boundary) conditions. The transport equation however reduces to a diffusion type equation if two conditions are met (a) if the medium's absorption is small in comparison to its scattering and (b) if the detected light has been scattered sufficiently and can be thus be considered emanating from an isotropic source. Both these conditions can largely experimentally satisfied – the first by selecting light with appropriate wavelengths, since the absorption and scattering properties of tissue are strongly wavelength dependent (for e.g. the near-infrared (NIR) wavelengths for tissue spectroscopy). The second condition may be satisfied by keeping the source-detector separations large in comparison to the mean scattering transport length of light in the medium of interest.

Under steady-state conditions (i.e. the source is CW or when the detected signal is time-integrated for longer than a few ns, in general) the diffusion equation for a semi-infinite homogenous medium with uniform optical properties the diffusion equation is written as:

$$[D\nabla^2 - \mu_a]\Phi(\vec{r}) = S(\vec{r}) \quad (7)$$

Here, $\Phi(\vec{r})$ represents the photon fluence rate (Wm^{-2}) as the net light energy at all points of interest in the medium, $S(\vec{r})$ describes the input source term, and D the medium's diffusion coefficient given by $D = 3[\mu_a + \mu_s(1 - g)]$, where μ_a is the medium's absorption coefficient, μ_s its scattering coefficient and g the single-scattering anisotropy coefficient. Under the formalism of DCS, the unnormalized field correlation $G_1(\vec{r}, \tau)$ is propagated using the diffusion equation as:

$$\left[D\nabla^2 - \mu_a - \frac{1}{3}\mu_s(1 - g)k_0^2\langle \Delta r^2(\tau) \rangle \right] G_1(\vec{r}, \tau) = S(\vec{r}) \quad (8)$$

The $\langle \Delta r^2(\tau) \rangle$ in Eq. (8) is the only additional term for the transport of the field correlation in a homogenous turbid medium and represents the mean-square displacement of the diffusing (or moving) particles, which add to the dynamics of the decay in the field correlation. Since closed form expressions of $\Phi(\vec{r})$ for Eq. (7) are readily available for several geometries, they can be used to calculate $G_1(\vec{r}, \tau)$ for measurements made in those geometries by replacing μ_a with $\mu_a - \frac{1}{3}\mu_s(1 - g)k_0^2\langle \Delta r^2(\tau) \rangle$.

Experimental Considerations

Experimentally, one has to make choices about the illuminating source, the delivery and collection optics to couple to the medium, and the detection system (see Fig. 1). Fig. 2 shows representative examples of experimental measurements obtained using a fiber-based DCS system while for different light sources, different detection fiber sizes and different types of scattering media.

Light Sources

Given that the theoretical formulation for modeling measurements assumes a monochromatic plane wave, DCS sources are usually single mode, stabilized, long-coherence length lasers operating in between 600–800 nm. In order for the experimental data to contain reliable dynamic information about the motion of scatterers, the temporal coherence length must be much longer the average path length of photons diffusing from the source and the detector placed on the tissue. Most applications reported with DCS use sources with coherence lengths longer than several meters.

Fig. 2 Measured representative intensity correlation curves (g_2) depicting data obtained for changing incident light source (left), changing detection fiber radius (middle) and different media (right). In all the plots, the solid line represents the autocorrelation detected using a fiber probe (source fiber radius = 200 μm , detector fiber radius = 6.5 μm and center-center distance of 1.5 mm) in reflection geometry on a turbid solid block. The dashed line in the left shows the correlation when the source was changed to a thermal halogen lamp. In the middle figure, the second fiber probe was used that had identical properties as the first probe but with detector radius of 200 μm while using the laser light for illumination. The dashed line in the right figure shows data from the first probe in contact with a human finger under laser illumination. These data indicate how both the intercept on the y-axis as well as the decay curves change across different conditions.

Coupling Optics

Although it is possible to make DCS devices capable of operating in a non-contact mode (i.e. coupling light to and from the medium without physical contact), the most practical method of using DCS for biomedical applications has been to couple light from the source to a medium (tissue site) using a source-fiber and obtaining diffusely scattered measurements using one or more detection fibers. The detection fiber is typically a low-mode fiber (ideally capable of monitoring fluctuations of a single speckle) while the source-fiber is a multi-mode fiber. The common end of this probe sets the source-detector geometry used to probe the sample volume and usually is larger than 5–10 mm for most DCS systems to stay within validity limits of diffusion theory.

Detection Systems

The ability to extract temporal correlations relies which not only requires sampling a fluctuating intensity signal at sampling rates of 10–100 MHz but also to store and process these signals to obtain the required intensity autocorrelation function. Traditional photon detection systems used an amplified photomultiplier tube (PMT) that with high enough response rates, while most recent systems employ detectors are small-area single photon avalanche photodiodes (APD). The digitized output sampled off the photodetector is to a digital correlator – usually a dedicated hardware board that computes required time correlation functions.

Modeling Measured Intensity Correlations

As described above, the experimental observations yield $g_2(\vec{r}, \tau)$ that is the intensity correlation for a measured at the detector situated at location $\vec{r}$ relative to the source and the medium. Thus, the analytical expressions for $G_1(\vec{r}, \tau)$ are converted to calculate $g_1(\vec{r}, \tau)$ which in turn is related to the experimental measurement of $g_2(\vec{r}, \tau)$ as:

$$g_2(\vec{r}, \tau) = 1 + \beta |g_1(\vec{r}, \tau)|^2 \quad (9)$$

Here, β is an experimental factor that is lesser than unity and depends on specific experimental configuration details such as the coherence length, coupled modes, dark noise and detection aperture size and thus is usually obtained as a free parameter during the fitting process. Besides β , experimentally measured data is fit to a specified functional formulation to extract parameters contributing to $\langle \Delta r^2(\tau) \rangle$. For example two commonly used models in tissue spectroscopy include diffusive flow where $\langle \Delta r^2(\tau) \rangle = 6D_B\tau$ where D_B is a diffusion coefficient, or random flow where $\langle \Delta r^2(\tau) \rangle = V^2\tau^2$ and V^2 is the second moment of the moving particle's velocity distribution. It is important to note that analytical fitting process is possible only by having estimates for the optical absorption and scattering coefficients of the medium, at the wavelength of the incident source.

Applications to In Vivo Tissue Sensing

Fiber-based DCS measurements have been obtained across a variety of clinical settings to address problems in monitoring progress of treatments, for monitoring cerebral blood flow during ischemia and for assessment of wound healing. Ultimately, the largest factor of contrast in biological tissues for the decorrelation of the measured intensity autocorrelations is attributed to the motion

of red blood cells in the vascular system. Thus, nearly any health application that requires monitoring of blood flow and its relative changes across perturbations could potentially use DCS a simple, non-invasive clinical adjunct.

DCS has been explored to investigate tissue perfusion since angiogenesis (i.e. the growth of new blood vessels) is now believed to be a marker of tumor growth and progression. Further, since treatments of tumors including chemotherapy and photodynamic therapy would be expected to impact blood flow and its dynamics during such treatments, DCS measurements have been applied to investigate these changes longitudinally in cancers of the prostate, breast and of the head and neck. In many cases DCS has been shown to provide an early indicator of treatment response (and failure). Given that traditional therapy monitoring techniques that include methods such as PET, MRI or CT, which many times are not accessible or amenable for use, DCS may provide a convenient, clinically-adoptable alternative.

DCS has also been used in applications to monitor cerebral blood flow – such monitoring studies were focused particularly on investigating perfusion rates and changes in the brain during ischemic strokes. An ischemic stroke the most common type of hemorrhagic stroke where a blood clot in the body constricts or depletes blood supply to certain regions of the brain. Since such a blockage would result in markedly different perfusion rates, DCS was an appropriate candidate for continuous and non-invasive blood in patients.

Other clinical applications of DCS have explored monitoring patient recovery from a traumatic wound injury, monitoring the blood supply to maxillofacial autographs during early stages of transplant, and monitoring the blood supply to skeletal tissues and muscles during certain high-intensity activities such as exercise. Several of these studies that employ DCS for measurement of tissue perfusion have been validated against clinically used “gold-standards” for flow-monitoring such as CT and MRI.

Preliminary and current data in clinical trials is promising for the field of non-invasive biomedical optical sensing. With an increasing number of studies showing successful applications of dynamic light scattering spectroscopy for in vivo and real-time monitoring of blood flow in tissues, it is likely that DCS-based devices will become more widespread. These application areas will benefit if DCS devices become commercially available as out-of-the box instruments and could become a routine and important tool used for sensing in vascular function or dysfunction in humans.

Introduction. The Janus Face of Photomedicine

Janus (or Ianus) was the Roman god of beginnings, gates, transitions, time, doorways, passages, and endings. He is usually depicted as having two faces looking in opposite directions, since he looks to the future and also to the past ([Fig. 1](#)). It is thought that the month of January was named for Janus (Ianuarius) because he presided over the ending of one year and the beginning of the next. Janus also presided over the beginning and ending of conflict, and hence over war and peace. The doors of his temple were open in time of war, and closed to mark the onset of peace. The most famous temple to Janus in Rome is called the Ianus Geminus, or “Twin Janus.” When its doors were open, neighboring cities knew that Rome was at war. As a god of transitions, he had functions pertaining to birth and to journeys and exchange.

The two-faced nature of the Roman God, Janus has become inextricably linked with many aspects of biology and medicine. The concept of a process, mechanism, treatment, or drug having both good and bad effects is so widespread and pervasive, that the analogy of Janus has been seized upon for a variety of reasons. Perhaps the best-known application of the Janus name in biology, is Janus kinase (JAK), which represents a family of intracellular, non-receptor tyrosine kinases that transduce cytokine-mediated signals via the JAK-STAT pathway. They were initially named “just another kinase” 1 and 2 (since they were just two of a large number of discoveries in a PCR-based screen of kinases ([Wilks, 1989](#))), but were ultimately published as “Janus kinase”. The name was taken from the two-faced Roman god of beginnings and endings, Janus, because the JAKs possess two near-identical phosphate-transfer domains. One domain mediates the kinase activity, while the other negatively regulates the kinase activity of the first domain.

We intend to show in this chapter that light therapy has many characteristics that can accurately be described as a “two-faced” or “Janus effect”. Depending on whether or not light is combined with a non-toxic photosensitizing dye (photodynamic therapy), and on the overall dose of light (energy density and power density), light is able to kill just about anything that is living such as cancers, microorganisms, blood vessels, parasites, pests, unwanted tissues etc, etc. On the opposite side of the coin (or perhaps on the other side of Janus’ face), light of the correct wavelength (photobiomodulation) and at the right dose (generally accepted to be “low” as in “low level laser therapy”) can have exactly the opposite effect, being able to heal, regenerate, protect, revitalize and restore any kind of dead, damaged, stressed, dying, degenerating cells, tissue, or organ system. Between the bad destroying face of photodynamic therapy, and the good healing face of photobiomodulation, it may well be concluded that indeed it can be said “all diseases can be treated with light”.

Photodynamic Therapy – The Killer

Photodynamic therapy (PDT) is the combination of non-toxic dyes and harmless visible light that combine together in the presence of oxygen to produce highly toxic reactive oxygen species (ROS) that can kill unwanted cells like cancer cells and pathogenic microorganisms ([Hamblin and Mroz, 2008](#)). PDT was discovered over one hundred years ago in 1900 when Oscar Raab (a medical student working with Herman von Tappeiner) on the toxicity of acridine dyes to protozoa. Raab realized that the

Fig. 1 Different depictions of the two-faced Roman god Janus.

variable results he obtained in his experiments using acridine orange and paramecia, could be attributed to variations in the level of ambient sunlight on the days when the experiments were performed. von Tappeiner and a dermatologist named Jesionek published the first report (just 3 years after Raab's initial paper) describing the use of 1% eosin solution painted on the skin, with white light illumination to successfully treat patients with basal cell carcinoma of the skin. In the decade that followed, von Tappeiner's group showed that this "photodynamic" effect required the simultaneous presence of a photosensitizer, light, and oxygen to mediate cellular toxicity. Freiderich Meyer-Betz then performed the first human trial of hematoporphyrin-mediated PDT by injecting himself with 200 mg of the drug and standing in sunlight.

It was however not until 1978 that Thomas Dougherty and his colleagues at Roswell Park Cancer Institute (RPCI) reported the first large-scale trial of PDT in human patients with cancer (Cengel *et al.*, 2016). In total, 113 primary and metastatic skin tumors were treated in 25 patients with diagnoses ranging from malignant melanoma to cutaneous T-cell lymphoma to metastatic breast and endometrial cancers. Many of those tumors were recurrent or had progressed after multiple cytotoxic chemotherapy agents and had failed local ionizing radiotherapy.

Since those early days PDT has continued to progress and has significantly widened the range of diseases and disorders that can be treated (Hamblin and Mroz, 2008), in addition to cancer (Agostinis *et al.*, 2011). The ROS produced during PDT can rapidly and completely kill any type of pathogenic microorganism, whether it be different classes of bacteria, viruses, yeasts, filamentous fungi, parasites (such as *Leishmania*), and also remove unwanted tissue such as atherosclerotic plaque, undesirable blood vessels, and scars.

Mechanisms of PDT

Fig. 2 shows the mechanisms that operate during PDT in a so-called Jablonski diagram. The ground state PS has two electrons with opposite spins (singlet state) in the lowest energy molecular orbital. Following the absorption of light (photons), one of these electrons is boosted into a higher-energy orbital but retains its spin (first excited singlet state). This is a short-lived (nanoseconds) species and can lose its energy by emitting light (fluorescence) or by internal conversion into heat. The fact that most PS are fluorescent has led to the development of sensitive assays to quantify the amount of PS in cells or tissues, and allows in vivo fluorescence imaging in living animals or patients to measure the pharmacokinetics and distribution of the PS. The excited singlet state PS may also undergo the process known as intersystem crossing whereby the spin of the excited electron inverts to form the relatively long-lived (microseconds to milliseconds) excited triplet-state that has both electron spins parallel. The long life of the triplet state is attributed to the relative rarity of other triplet molecules with which it can interact.

The PS excited triplet can undergo three broad kinds of reactions that are usually known as type I and type II (see Jablonski diagram in Fig. 2). Firstly, in a type I reaction, the triplet PS can gain an electron from a neighboring reducing agent. In cells these reducing agents are commonly either nicotinamide adenine dinucleotide (NADH) or NAD-phosphate, reduced form (NADPH). The PS is now a radical anion bearing an additional unpaired electron ($PS^{\bullet-}$). Alternatively two triplet PS molecules can react together involving intermolecular electron transfer to produce a pair consisting of a radical cation and a radical anion. The PS radical anions may further react with oxygen to carry out an electron transfer to produce reactive oxygen species, in particular superoxide anion. The damaging effects of superoxide are relatively mild, however it can cause much more oxidative damage when it reacts with itself to produce hydrogen peroxide and oxygen, in the process called "dismutation". Hydrogen peroxide, can add to an organic (carbon-containing) substrate and result in an oxidizing "chain reaction". This is common in the oxidative damage of fatty acids and other lipids. Hydrogen peroxide is important in the production of the highly reactive hydroxyl radical ($HO^{\bullet}$), by a second one-electron reduction mediated by $PS^{\bullet-}$. Superoxide will additionally react with nitric oxide ($NO^{\bullet}$) (also a radical) to produce peroxynitrite ($OONO^-$), another highly reactive molecule that can oxidize many functional groups and can also nitrate proteins on tyrosine residues.

Fig. 2 Jablonski diagram showing photochemical reactions that occur during PDT.

In a type II reaction, the triplet PS can transfer its energy directly to molecular oxygen (itself a triplet in the ground state), to form excited-state singlet oxygen. Type II processes are thought to best preserve the PS molecular structure in a repeatedly photoactivatable state, and in some circumstances a single PS molecule can generate 10,000 molecules of singlet oxygen. The PS can in some circumstances also react with the singlet oxygen it produces in a process known as oxygen-dependent photobleaching.

Singlet oxygen generated during type II photochemical reactions, is believed to be the most important molecule responsible for PDT-induced cellular damage (Henderson and Miller, 1986; Weishaupt *et al.*, 1976). However, because of the high reactivity and short half-life of singlet oxygen only molecules and structures that are proximal to the area of its production (areas of PS localization) are directly affected by PDT. The half-life of singlet oxygen in biological systems is < 40 ns, and, therefore, the radius of the action of singlet oxygen is of the order of 20 nm (Moan and Berg, 1991). In singlet oxygen the spin restriction that reduces reaction rates of triplet oxygen with non-radicals is excluded. Consequently, singlet oxygen has an empty low-energy valence orbital that makes it a potent oxidizing/oxygenating agent compared to its ground-state counterpart. Singlet oxygen interacts with molecules via two essential mechanisms: physical interactions with quenchers or chemical reactions with biomolecules and scavengers. In the first phenomenon singlet oxygen transfers its excitation energy to an acceptor molecule (quencher) promoting it to an excited state while oxygen returns to ground-state. The excited quencher can be cleaved forming new products or react with biomolecules and cause damages. Antioxidant molecules, such as carotenoids, can alternatively dissipate the energy quenched from singlet oxygen in the form of heat, preventing any sort of oxidative damage. Even though, most carotenoids are very hydrophobic substances and exclusively accumulate in cell membranes (Kearns, 1971).

Singlet oxygen mainly reacts with molecules containing thiol groups or double bonds. Hence, it presents more restricted reaction patterns in relation to free radicals produced by type I reactions. Carbon and nitrogen atoms form double bonds sharing two electrons with opposite spin orientation. Note that ground-state oxygen cannot receive those two paired electrons because both low-energy orbitals are already occupied by one unpaired electron. Since singlet oxygen has an empty low-energy orbital, it has no restrictions to react with double bonds (Bland, 1976; Kearns, 1971).

Type I photodynamic reactions start off via donation of one electron from the excited PS ($^3\text{PS}^*$) to O_2 producing superoxide radical ($\text{O}_2^{\bullet-}$) by a 1-electron reduction, and then going on to form hydrogen peroxide by a 2-electron reduction of O_2 that can yet produce more radicals. Radical species are typically paramagnetic because they carry one or more unpaired electrons in valence shell orbitals. This feature makes radicals particularly reactive. They are susceptible to react with several possible biomolecules passing the unpaired electron to another molecule also turning it into radical species or releasing another free radical. Therefore, a single radical formed can initiate chain reactions that lead to damage of several biomolecules. Radical reactions are rather unspecific and can attack lipids, sugars, proteins and nucleic acids forming radical moieties within these biomolecules. Such radical moieties then allow biomolecules to react with each other forming cross-links between them (e.g. lipid-lipid, lipid-protein, protein-DNA, etc.). Either radical addition to biomolecules through hydroxylation and peroxidation or cross-link formation will potentially inhibit biomolecular function. As direct consequences, proteins are denatured, polysaccharides cleaved, nucleic acids are damaged, membranes become less fluid, more porous and may even be disrupted. Proteins can yet be targeted for proteasome degradation.

Lipid peroxidation represents a critical source of cellular damage that often leads to necrosis. Because hydroxyl radicals are extremely reactive non-polar species they can rapidly abstract a hydrogen atom from saturated lipids forming lipid radicals ($\text{L}^\bullet$). Secondly, ground-state oxygen molecules can add to the lipid radical forming peroxy radicals that can subsequently react with other lipids that will propagate chain reactions until recombination or dismutation reactions take place. Since cell membrane consists of double layer of phospholipids, closely interacting with each other and with membrane proteins, radical chain reactions can spread through the membrane causing serious damages that ultimately result in necrosis via membrane rupture (Halliwell and Chirico, 1993). To minimize the extent of this type of damage, nearly all cells in nature accumulate antioxidants molecules and enzymes in membranes preventing the propagation of radical reactions (Buettner, 1993; Halliwell and Gutteridge, 2015). All amino acids, including when modified, are susceptible to damage caused by radical reactions. Protein function is highly associated to its structural conformation, that is resultant of the chemical characteristics of each amino acid in the polymeric chain. Of course, some amino acids are more important than others for protein structure and active site, however, the oxidation of any amino acid in the chain can potentially alter protein conformation and consequently its function. In the case of membrane proteins, note that transmembrane domains are constructed with chains of hydrophobic amino acids. If these amino acids are oxidized they become more hydrophilic and may detach from cell membrane to be solvated by water either in the cytosol or the extracellular media (Davies, 2016).

There are an astonishing array of known compounds that can act as photosensitizers in PDT. In the interests of space we can only give a few examples of their chemical structures here. Fig. 3 shows the structure of Photofrin (the first PS to be clinically used for various cancers, and still one of the commonest). Foscan or Temoporfin (*m*-tetrahydroxyphenylchlorin) is another PS that is commonly used in the clinic to treat different types of cancers. Methylene blue is a phenothiazinium dye, which is the most commonly used PS to treat infections.

Antimicrobial Photodynamic Inactivation and PDT for infectious Disease

Rise of antibiotic resistance

Together with vaccines and public health measures to control transmission of communicable diseases, antibiotics have helped to dramatically reduce mortality from infectious disease during the 20th century (Guyer *et al.*, 2000). However, the continuing global challenge of pathogens such as influenza, tuberculosis, and malaria, as well as the emergence of human

Fig. 3 Chemical structures of three clinically used PS: Photofrin, Foscan, Methylene blue.

immunodeficiency virus, means that infectious disease remains an important problem (Fauci and Morens, 2012). The real value of antibiotics goes beyond simply preventing death and illness due to infection, considering that antibiotics also permit the serious iatrogenic assault on the immune system (immunosuppression) that may occur during cancer treatment or in organ transplantation, where antibiotics have helped to keep surgical complication rates down (Youngblood *et al.*, 2002). Therefore, antibiotics are an extremely valuable resource across the whole spectrum of modern medicine (Smith and Coast, 2013). However, multidrug-resistant (MDR) and pandrug-resistant (PDR) bacterial strains and the related infections they cause, have become emerging threats to public health throughout the world (Kraus, 2008). These infections are associated with an approximately two-fold higher death rate, and with considerably prolonged hospital stays (Munoz-Price *et al.*, 2013). The infections caused by antibiotic resistant microbial strains are often exceptionally hard to treat due to the limited range of therapeutic options (Yoneyama and Katsumata, 2006). Therefore, there is a need for an immediate and all-out search for alternative antimicrobial methods against MDR strains, towards which no resistance likely to develop (Hamblin and Hasan, 2004; Maisch, 2007; Maisch *et al.*, 2011). Recently, Karen Bush *et al.* pointed out that novel non-antibiotic approaches for the prevention and treatment of infectious disease should be considered high-priority international research and development goals (Bush *et al.*, 2011).

In 2015 the O'Neill report garnered much international attention when it delivered the alarming forecast that by 2050 (if nothing were done to stem the growth of MDR bacteria) there would have been 300 million premature deaths that would have cost the world economy \$100 trillion (O'Neill, 2015). One of the most promising and innovative approaches to kill drug-resistant bacteria and treat resistant infections is antimicrobial photodynamic inactivation (aPDI).

History of aPDI

The initial discovery of the PDT/PDI effect was made by in 1900 by a PhD student called Oscar Raab working in the laboratory of Prof Hermann von Tappeiner in Munich, Germany. Raab was studying the toxicity of acridine dyes towards paramecia (a single-celled ciliated protozoan microorganism living in ponds). Raab found that his results were quite variable, but recognized that the apparent toxicity depended on the time of day, and the amount of light coming through the laboratory window, with no toxicity when the experiment was done in the dark. There were sporadic reports of killing of different kinds of microorganisms (bacteria, fungi and viruses) for the next 90 years, but it wasn't until 1990 that major progress was made.

Pathogen classification and PS structure

In the 1990s it was observed that there was a fundamental difference in susceptibility to PDT between Gram (+) and Gram (−) bacteria. It was found that in general neutral or anionic PS molecules are efficiently bound to and photodynamically inactivate Gram (+) bacteria whereas they are bound to a greater or lesser extent only to the outer membrane of Gram (−) bacterial cells but do not inactivate them after illumination (Malik *et al.*, 1992). The high susceptibility of Gram (+) species was explained by their physiology as their cytoplasmic membrane is surrounded by a relatively porous layer of peptidoglycan and lipoteichoic acid that allowed PS to cross. The cell envelope of Gram (−) bacteria consists of an inner cytoplasmic membrane and an outer membrane, which are separated by the peptidoglycan-containing periplasm (Fig. 4). The outer membrane forms a physical and functional barrier between the cell and its environment. In the outer membrane several different proteins are present, some of them function as pores to allow passage of nutrients, whereas others have an enzymatic function or are involved in maintaining the structural integrity of the outer membrane and shape of the bacteria.

Fig. 4 Cell wall structures of (A) Gram-positive bacteria; (B) Gram-negative bacteria; (C) Fungi.

Then several groups of workers devised approaches that would allow PDI of Gram (–) species. The group in Israel consisting of Malik, Nitzan and co-workers (Nitzan *et al.*, 1992) used the polycationic peptide polymyxin B nonapeptide (PMBN) which increased the permeability of the Gram (–) outer membrane and allowed PS that are normally excluded from the cell to penetrate to a location where the reactive oxygen species generated upon illumination to execute fatal damage. PMBN does not release LPS from the cells but “expands” the outer leaflet of the membrane allowing PS such as deuteroporphyrin (DP) to penetrate and allow PDI of *E. coli* and *P. aeruginosa*. They demonstrated an interaction between PMBN and DP in solution and speculated that this binding assisted the penetration. They used this method to kill a multi-antibiotic resistant strain of *Acinetobacter baumannii* and found that DP seemed to work much better in concert with PMBN than many other PS including porphyrins, phthalocyanines and merocyanine 540 (Nitzan *et al.*, 1998). They also found that the growth medium of the bacteria made a large difference in their susceptibility to PDI, with the high protein brain-heart infusion leading to less killing than the low protein nutrient broth. They found that the type of protein present in the medium made a difference in addition to the concentration. A similar approach was taken by Bertoloni *et al.* (1990) who found that the use of tris-ethylenediamine tetra-acetic acid (EDTA) to release LPS or the induction of competence with calcium chloride sensitized *E. coli* and *Klebsiella pneumoniae* to PDI by haematoporphyrin or zinc phthalocyanine.

A second approach adopted by several groups is to use a PS molecule with an intrinsic positive charge. The groups of Wilson (2004) and Wainwright (1998) have used the phenothiazinium salts such as MB and toluidine blue O to carry out PDI of a large range of bacteria both Gram (+) and Gram (–). The group in Italy led by Jori have used cationic porphyrins (meso-tetra (N-methyl)-4-pyridyl)-porphine tetraiodide and tetra-(4N,N,N-trimethyl-anilinium)-porphine to photoinactivate Gram (–) species such as *Vibrio anguillarum* and *E. coli* (Merchat *et al.*, 1996). They found that washing the loosely bound PS from the cells before illumination decreased the killing and explained this finding by supposing that the first dose of light on PS bound to the outside of the outer membrane causes an initial limited photodamage that then allows further penetration of the PS. The group in Leeds, UK led by Brown has used cationic phthalocyanines for PDI of Gram (–) bacteria (Minnock *et al.*, 1996). They investigated

E. coli DH5a and in particular the mechanism of uptake. They found that incubation with PPC in the dark led to increased sensitivity of the bacteria to hydrophobic but not hydrophilic antibiotics. Incubation with PPC also led to increased uptake of radiolabeled protoporphyrin that was reversed in the presence of up to 50 mM Mg^{++} ions. These observations were consistent with the uptake of PPC proceeding through the self-promoted uptake pathway (see next section).

However there are other reports of PDI of Gram (–) bacteria in which it is clear that the PS does not have to penetrate the bacterium to be effective, or indeed even come into contact with the cells. According to these papers, if singlet oxygen can be generated in sufficient quantities near to the bacterial outer membrane it will be able to diffuse into the cell to inflict damage on vital structures. In one set of studies, the bacteria were separated from the PS by a layer of moist air and singlet oxygen in the gas phase was generated and allowed to diffuse across the gap before contacting the bacteria (Valduga *et al.*, 1993). Gram (–) species were harder to kill than Gram (+), and the intracellular content of carotenoids was found to protect the bacteria from photo-inactivation. In another study, the PS Rose Bengal was covalently bound to small polystyrene beads that were allowed to mix with the bacteria in suspension (Dahl *et al.*, 1989).

How can these two conflicting sets of findings; one pointing out the necessity for PS penetration into Gram (–) bacteria, and the other pointing out that extracellular generated singlet oxygen is effective, be reconciled? One possibility is that indeed singlet oxygen can diffuse into bacteria producing fatal damage if it is produced at the outer surface or in solution in close proximity. The diffusion distance of singlet oxygen in solution has been estimated to be approximately 20–100 nm (Klaper *et al.*, 2016). The failure of some PS that bind to Gram (–) species to produce any killing however, must mean that the reactive species produced on illumination were unable to diffuse inward to sensitive sites. The fact that these PS can lead to efficient PDI of Gram (+) species shows that the molecules have not undergone any conformational change that has rendered the PS no longer photoactive. Hence we hypothesize that PS that operate chiefly via Type I mechanisms need to penetrate the Gram (–) outer membrane, while those that act mainly by Type II PS may not, and that the former may be more efficient.

Virulence

Photodynamic therapy is one of the few antimicrobial therapies, that can not only kill microbial cells, but can also destroy many virulence factors that microbial cells produce in order to facilitate their adherence, invasion, survival, and toxicity in host cells and tissues. These virulence factors are usually biomolecules such as proteins, lipids and carbohydrates, that are just as susceptible to oxidative damage by the ROS produced during PDT, as the microbial cells themselves.

PDT for infectious disease

In recent years the application of PDT for the treatment of localized infections called aPDI has steadily increased in popularity (Fig. 5). This application can superficially appear much simpler than the more well-recognized application of PDT for cancer treatment (see below). The complexity of dealing with the vascular effects of PDT is absent, because the PS is almost always topically applied into/onto the infected area of tissue. Moreover, there have not as yet been many reports about activation of the immune system being triggered after carrying out aPDI for an infectious disease (see later).

So it is generally assumed that a PS with cationic charges, which is more or less selective for microbial cells, is injected or otherwise topically applied into the infected area, where it binds to the microbial cells after a short-drug light interval, in order to

Fig. 5 Localized infections that could possibly be treated by PDT.

reduce the uptake of the PS by the surrounding host cells, and increase selectivity. However what is not often realized is the big difference between tumors and infections. In tumors all the surrounding tissue is considered to be undesirable, diseased and in need of removal. This is completely different to the case of an infection. An infection is defined as greater than 10(5) CFU of microbial cells per gram of tissue. The mass of 10(5) CFU of bacterial cells is approximately 1 µg. So the ratio between the mass of the bacterial tissue and the mass of the host tissue is in the region of 1 to 1,000,000 (Hamblin and Dai, 2010). So in sharp contrast to the case, where in tumors the goal is to destroy 100% of the surrounding tissue, in infections the goal is to destroy only 0.0001% of the surrounding tissue (just the bacterial cells). For this to be anyway near feasible the selectivity of the PS for bacteria has got to be exquisite so that 999,999 PS molecules out of every million bind to their target bacteria and not to the host cells. As can be imagined this is rather unlikely. However the situation is not as dire as the foregoing has made it out to be. The reason for this is that a short drug light interval is used for aPDI and even if the selectivity for bacteria over host cells is somewhat less than 1 million to 1, then the poly-cationic nature of the PS means that it is fairly slow to be taken up by host mammalian cells. So if light is delivered after say 30 s from topical delivery of the PS, it can be reasonably save to assume that not many of the surrounding host cells would be killed.

There have not been many reports of damage to host tissue being caused by aPDI in animal models. One study (Gad *et al.*, 2004) did use a model of a subcutaneous abscess caused by Gram-positive bioluminescent *Staphylococcus aureus* injected into the mouse thigh muscle. A small volume of PS solution was injected into the infected area and light was shone as a spot onto the surface. Two different PS were compared, the polycationic conjugate, poly-L-lysine chlorin(e6) (pL-ce6), and the anionic PS, free chlorin(e6). Both PS were equally effective in destroying the bacteria as judged by non-invasive bioluminescence imaging. However the non-bacterial targeted free chlorin(e6) caused more damage to the surrounding mouse thigh muscle as measured by a leg function test. The bacterial-targeted pL-ce6 was able to kill the bacteria without damaging the thigh muscle.

There has only been one report of activation of the immune system after PDT, when used against an infection in an animal model (Tanaka *et al.*, 2012). This involved injection of bioluminescent *S. aureus* into the mouse knee to produce a form of septic arthritis. When methylene blue was injected into the knee and 660 nm light delivered to the surface, the bacteria were killed in a similar manner to the experiment described above. However when the MB PDT was carried out before the bacteria were injected into the knee, rather than afterwards, an interesting observation was made. PDT carried out 24 h (but not 2 h) before infection protected the mice from developing a severe knee infection when the bacteria were subsequently injected, as shown by the fact that the infection resolved earlier (Tanaka *et al.*, 2012). This effect was dependent on neutrophils in the mouse knee as demonstrated by use of several blocking antibodies and inhibitors. Although there was no immediate influx of neutrophils into the mouse knee immediately after PDT, the neutrophils did appear to be “primed” to react quicker to attack the bacteria, once these were injected into the knee joint. Therefore, PDT of the mouse knee could be envisaged as a ‘non-specific vaccination procedure’, which could in principle be used in cases of orthopedic surgery, which might be considered high-risk for infection.

As mentioned above, for many years PDT was studied as a cancer therapy by designing PS that could be administered either systemically (by intravenous injection) or applied topically (e.g. aminolevulinic acid), and some time later the tumor would be irradiated with light (either as a surface spot or by insertion of interstitial fiber optics) (Agostinis *et al.*, 2011). However starting in the 1990s it was realized that PDT could also exert a powerful antimicrobial effect, if PS could be designed that could selectively bind to microbial cells, while not binding to host mammalian cells (Malik *et al.*, 1992). The best way of achieving this goal of antimicrobial photodynamic inactivation (aPDI) was to ensure that the PS had a pronounced cationic charge, as it was realized that microbial cells in general have a more pronounced negative charge compared to mammalian cells and cationic PS will bind selectively. Moreover the binding of the PS to the microbial cells is relatively rapid, while uptake of the cationic PS by mammalian cells is slow, thus giving good selectivity when a short drug-light interval (few minutes) is employed (Dai *et al.*, 2009). The advantages of aPDI as a potential clinical antimicrobial therapy were bolstered when it was realized that aPDI works equally well regardless of the antibiotic resistance status of the microbial cells (Vera *et al.*, 2012) and moreover, that aPDI has (so far) not been shown to produce resistance in bacteria (Maisch, 2015) even after 20 successive cycles of partial killing followed by regrowth (Giuliani *et al.*, 2010). Another advantage of aPDI is that the PS is applied topically or locally into the infected area. Many chronic infections involve a build up of microbial biofilms, into which it is now well-recognized, that systemically administered antibiotics fail to penetrate. However, aPDI has been shown to kill biofilm-grown cells both in vitro and in vivo (de Melo *et al.*, 2013). This anti-biofilm application has found particular application in dental infections such as periodontitis (Kikuchi *et al.*, 2015) and peri-implantitis (Vohra *et al.*, 2014). Moreover, infections in burns or damaged tissue suffer from a compromised blood supply, so systemically administered antibiotics fail to reach the site of infection in sufficient concentrations. The killing of microbial cells with aPDI is rapid (seconds) while the action of antibiotics can take hours or days, giving a potential advantage against fast-spreading infections such as necrotizing fasciitis. Moreover the broad-spectrum nature of aPDI means that treatment can be instituted before the infectious agents have been identified (Ferreyra *et al.*, 2016). Although many infections can occur deep inside the body, it is now possible to deliver both PS and light to almost any anatomical region, via endoscopes and narrow-diameter interstitially-inserted needles and fiber optics (Gad *et al.*, 2004).

PDT for Cancer

Cancer is still the most often-discussed indication for PDT and many papers have been published discussing modes of cell death in vitro (Fig. 6), and investigating pharmacokinetics and tumor response in vivo.

Fig. 6 PDT causes damage to biomolecules and intracellular organelles.

Cellular mechanisms of PDT

PDT and apoptosis

Apoptosis is a very complex, multi-step, multi-pathway cell-death program that is genetically encoded in every cell of the body (Pettigrew and Cotter, 2009). It can be initiated either through the activation of death receptors or the mitochondrial release of cytochrome c (Rustin, 2002). Both events eventually lead to activation of caspase cascades. Caspases are cysteine aspartic acid proteases and some members of the family are 'executioner caspases' such as caspase-3, -6 and -7 (Gougeon and Kroemer, 2003; Perfettini and Kroemer, 2003). The active executioner caspases cleave cellular substrates, which leads to characteristic biochemical and morphological changes observed in dying cells (Rathmell and Thompson, 1999). Chromatin condensation and nuclear shrinkage; cleavage of the inhibitor of the DNase CAD (caspase activated deoxyribonuclease) causes DNA fragmentation. Cleavage of cytoskeletal proteins leads to cell fragmentation and formation of apoptotic bodies (Savill and Fadok, 2000). The apoptotic process is tightly controlled by various proteins (Cotter, 2009; Okada and Mak, 2004). It is well known that resistance of tumor cells to apoptosis might be an essential feature of cancer development thus, modulation of the key elements of apoptosis signaling may directly influence tumor-cell death induced by various forms of cancer therapy (Igney and Krammer, 2002a,b).

PDT is thought to induce photodamage to Bcl-2 and related antiapoptotic proteins and activate the proapoptotic members of the family (Oleinick *et al.*, 2002). Alteration in expression of members of Bcl-2 family proteins following PDT has been reported in various cell lines and tumors. During apoptosis, the pro-apoptotic proteins Bax and Bak oligomerize in the mitochondrial outer membrane and probably disturb its integrity, leading to release of pro-apoptotic signaling molecules like cytochrome c, which then allows the activation of caspase 9 (Cory and Adams, 2002).

Accumulating evidence suggests that PDT is an efficient inducer of apoptosis in many cancer cell lines, whereas cells that lack the ability to efficiently undergo apoptosis are not protected from the lethal effects of PDT. Bax was not found to be essential for Photofrin-PDT induced apoptosis in human lung adenocarcinoma cells (ASTC-a-1) (Wu *et al.*, 2011). In the absence of Bax/ Bak, autophagy appears to be predominantly responsible for cell death following PDT with different photosensitizers (Buytaert *et al.*, 2006a,b; Kessel, 2006).

PDT produces a level of oxidative stress that can result in activation and translocation of the transcription factor NF- κ B to the nucleus, as originally shown for treatment of L1210 murine leukemia cells with Photofrin and light (Ryter and Gomer, 1993). NF- κ B provides an anti-apoptotic signal or cell survival pathway for cells exposed to PDT (Coupienne *et al.*, 2010).

PDT and necrosis

Necrotic cell death has been described as a violent and rapid form of degeneration affecting large fractions of cell populations, characterized by cytoplasmic swelling, destruction of organelles and disruption of the plasma membrane, leading to the release of intracellular contents and consequent inflammation (Danial and Korsmeyer, 2004).

Necrosis has been referred to as accidental cell death, caused by physical or chemical damage and has generally been considered an unprogrammed process (Kitsis and Molkentin, 2010). It is characterized by formation of a pyknotic nucleus, cytoplasmic swelling, and progressive disintegration of cytoplasmic membranes, all of which lead to cellular fragmentation and release of material into the extracellular compartment. In necrosis, decomposition is principally mediated by proteolytic activity, but the precise identities of proteases and their substrates are poorly defined (Proskuryakov and Gabai, 2010).

Studying the factors and parameters that cause cellular necrosis after PDT is not as easy as studying those factors which lead to apoptosis. The crucial factors in determining the type of cell death, e.g. apoptosis or necrosis following PDT are: the cell type, the presence of an intact set of apoptosis machinery, the subcellular localization of the PS, the light dose applied to activate it locally, and the oxygen partial pressure (Buytaert *et al.*, 2007). One factor that can be agreed upon by all commentators is that high dose PDT (either a high photosensitizer concentration or a high light fluence or both) tends to cause cell death by necrosis, while PDT administered at lower doses tend to predispose cells towards apoptotic cell death.

It is possible that high doses of PDT can photochemically inactivate essential enzymes and other components of the apoptotic cascade such as caspases. For instance, Lavie and coworkers (Lavie *et al.*, 1999) used the perylenequinones (hypericin and dimethyl tetrahydroxyhelianthrene) and found high dose PDT inhibited apoptosis by interfering with lamin phosphorylation, or by photodynamic cross-linking of lamins.

Xue *et al.* (2001) compared Pc4-mediated PDT of MCF7 cells that lack caspase 3 with the same cell line with caspase 3 transfected back in. They found apoptotic indicators only in the caspase expressing cells which also showed more loss of viability by an assay involving reduction of a tetrazolium dye; however both cell lines showed an equal degree of cytotoxicity by a clonogenic assay.

Dahle, Steele and Moan reported (Dahle *et al.*, 1999) that the mode of cell death induced by PDT depended on cell density. They seeded Madison Darby canine kidney II cells (MDCK II) at two different densities and incubated them with meso-tetra(4-sulfonatophenyl)porphine (TPPS4) for 18 h, washed and irradiated with blue light. Four hours later the cells were studied by fluorescence microscopy. With <55% total cell death the apoptotic fraction was significantly higher for cells in confluent monolayers than for cells growing in microcolonies at equitoxic doses. Confluent cells were 2.9 times more sensitive than cells in microcolonies partly due to a 1.5 times higher uptake of TPPS4 in monolayer cells. The difference in mode of cell death for the different cell densities was not related to any observable difference in subcellular localization pattern of TPPS4 at equitoxic doses of PDT.

PDT and autophagy

Autophagy is a catabolic cellular mechanism that allows the cell to maintain a balance between the synthesis, degradation, and recycling of cellular products (Mathew *et al.*, 2007). A variety of autophagic processes exist, all of which involve the lysosomal degradation of the cellular organelles and proteins. The most well-known mechanism proceeds in the following manner: A double membrane structure called autophagosome surrounds the target region, creating a vesicle that separates its contents from the rest of the cytoplasm. This vesicle is then transported and fused to the lysosome, forming a structure called the autophagolysosome, the contents of which are subsequently degraded by lysosomal hydrolases (Kroemer and Jaattela, 2005). Besides facilitating the disposal of unwanted proteins, organelles, and invading microorganisms, autophagy also allows a cell to reallocate its nutrients from unnecessary processes to life-essential ones in times of starvation or stress. The term “autophagy” was coined in 1963 at the Ciba Foundation Symposium on Lysosomes, where it was used to describe the presence of membrane vesicles that contain disintegrating organelles and cytoplasm components. Evidence soon confirmed that autophagy is an adaptive, energy-generating process. Molecular control of autophagy came into focus in the late 1990s. Signaling pathways governing this process became better understood after the identification of the target of rapamycin kinase (TOR), which controls cell growth and protein synthesis (Bjornsti and Houghton, 2004).

It is still unclear exactly how autophagy affects the outcome of PDT (Kessel, 2006; Kessel *et al.*, 2006; Reiners *et al.*, 2010). In general, mammalian cells use autophagy as a defense against ROS mediated damage by clearing the cell of damaged organelles (Scherz-Shouval *et al.*, 2007). Depending on the type of ROS and degree of oxidative injury, PDT may stimulate autophagy (Sasnauskiene *et al.*, 2009) that either acts in a cytoprotective manner or induces autophagic cell death (Scherz-Shouval and Elazar, 2007). Autophagy may play a role in PDT induced apoptosis, but the two processes can also occur independently of one another (Kessel and Oleinick, 2009). A study done on murine leukemia L1210 cells found that a wave of autophagy occurs right before apoptosis. (Kessel and Arroyo, 2007). It was also found that prevention of autophagy by silencing the Atp7 gene allowed photo-killing to occur at lower light doses. This observation is consistent with the theory that autophagy is a defense mechanism against PDT induced ROS (Kessel and Reiners, 2007). The situation is different for tumor cells that do not have the ability to undergo apoptosis through a deficiency in Bax or Bac, which regulate the apoptotic pathway. In these cells, PDT induced autophagy stimulates a necrotic, caspase-independent cell death (Buytaert *et al.*, 2006a). Suppression of autophagy in apoptosis-deficient cells resulted in the inhibition of cell death during PDT. In general, the induction of autophagy in PDT treated cells occurs independently of an apoptotic outcome. While autophagy seems to play a pro-survival role in tumor cells that are capable of apoptosis, it has been shown to promote death in cells that are apoptosis-deficient.

PS pharmacokinetics

When PS preparations are injected into the bloodstream they tend to bind to various serum proteins and this binding can dramatically affect their pharmacokinetics and biodistribution (Boyle and Dolphin, 1996). Different PS can have very different pharmacokinetics and this can directly affect the illumination parameters and particularly the pharmacokinetics will determine the drug-light interval (Agostinis *et al.*, 2011). Intravenously injected PS undergo a gradual transition from being bound to serum proteins, then becoming bound to endothelial cells, then they are bound to the adventitia of the vessels, then bound either to the extracellular matrix or to the cells within the tumor, and eventually they will be cleared from the tumor tissue by removal by lymphatic vessels or by blood vessels, and they will be excreted either by the kidneys or the liver. The effect of PDT on the tumor largely depends at which

stage of this continuous process light is delivered. The anti-tumor effects of PDT are divided into three main mechanisms. Direct tumor cell death by apoptosis or necrosis can occur, if the PS has been allowed to be taken up by tumor cells. Powerful anti-vascular effects can lead to thrombosis and hemorrhage in tumor blood vessels that subsequently leads to shut-down of tumor blood vessels, which kills the tumor by deprivation of oxygen and nutrients. Finally the release of damage associated molecular patterns (DAMPs) leads to acute inflammation and the release of cytokines (Garg *et al.*, 2011). The DAMPs, cytokines and stress response proteins induced in the tumor by PDT work together and lead to an influx of leukocytes that can both contribute to tumor destruction as well as to stimulate the immune system to recognize and destroy tumor cells even at distant locations.

When PS are injected into the bloodstream a certain sequence of events commences that can take very different lengths of time to reach completion, for PS with different chemical structures. Firstly, depending on the delivery solvent or vehicle that is used for the PS injection, the PS must come to equilibrium with the components of the circulating blood. This can involve the PS disaggregating from itself being released from its delivery vehicle and binding instead to various protein components of serum (see later). In addition the blood has many circulating cells (erythrocytes and leukocytes) that would in principle be available to bind injected PS (Maugain *et al.*, 2004). Secondly, the circulating PS must bind to the walls of the blood vessels, and it is thought that the nature of the various blood vessels in the tumor and in surrounding normal tissues that vary significantly in size, speed of blood flow, and physiological characteristics such as leakiness and tortuosity in tumors and various normal organs, governs to a great extent where the PS localizes or accumulates. Thirdly, the PS will penetrate through the wall of the blood vessel at a rate that probably depends on how strong the initial binding of the PS to the intimal surface was. PS that bind strongly to the blood vessel wall will take a longer time to cross the entire wall of the blood vessel, and those that have an initial weaker binding will pass through more quickly. Fourthly, after extravasation, the PS will diffuse throughout the parenchyma of the organ or tumor to which it has been delivered. If the organ happens to be the liver or other metabolically active organ, the PS may be subject to chemical changes by metabolic enzymes, but this is thought to be rather unlikely for most tetrapyrrole-based PS in common clinical use. Fifthly, the PS will eventually be eliminated from the tissue. Although this elimination has not been much studied, if the tissue containing the PS is a tumor or other non-metabolic organ, elimination will probably be by lymphatic drainage and the PS will then return into the general blood circulation via the thoracic duct. Sixthly, the PS will be excreted from the body. For the majority of PS in clinical use, excretion is from the liver into the bile and thence to the intestine where it is lost via fecal elimination. However entero-hepatic re-circulation, which is the term used for the re-absorption of the PS from the small intestine, back into the blood stream, has been reported for some PS.

Measurement of pharmacokinetics requires sequential measurements of PS concentration in tissue or other biological substance or fluid in order to construct temporal profiles that can be compared for different PS. This is frequently done for blood where samples can be readily removed in small amounts at frequent intervals and analysis then yields values of serum half-lives (first or second order) in minutes, hours or days. Alternatively, analysis of PS concentrations in urine or fecal samples can give terminal elimination half-lives. All these methods require a method of quantitatively analyzing PS concentrations in samples of biological material. The fact that the majority of PS used for PDT are also fluorescent, has led to the development of assays involving homogenization or dissolving the tissue or biological fluid and measurement of fluorescence in solution after centrifugation or extraction steps (Bellnier *et al.*, 1997). Calibration curves can be prepared with mixtures of known amounts of PS and weighed amounts of biological material. Care must be taken when these experiments are carried out on small rodents such as mice and rats because these animals accumulate a naturally red-fluorescent compound derived from chlorophyll in their diet that ends up in the skin and the digestive tract amongst other organs (Gudgin Dickson *et al.*, 1995). This can be avoided by feeding the animals a chlorophyll-free diet for enough time before the experiment to allow the interfering fluorescent compound to be eliminated (Allison *et al.*, 1994). In some cases the PS is quantified by a traditional analytical chemistry technique such as high performance liquid chromatography (Almeida-Lopes *et al.*, 2001). This method has the advantage of detecting possible metabolism products that have been formed from the originally pure PS after injection. Finally in some cases of experimental animal models, the PS has been presynthesized in the laboratory to include a radioisotope label (for instance carbon-14 or tritium) or a chelator can be attached that can bind a metal radioisotope and biological samples can then be quantified using a scintillation counter (Bellnier *et al.*, 1989; Little *et al.*, 1984; Schuitemaker *et al.*, 1993). An alternative approach to carrying out analysis of samples of biological material removed sequentially, is to use a continuous optical monitoring method to determine PS concentration in tissue based on fluorescence. In this approach a non-invasive or minimally invasive approach with fiber-based fluorescence detection systems can be used to measure the variation over time of a fluorescence signal linked to the PS of interest (Frisoli *et al.*, 1993). In some small animal models the skin can be removed from a subcutaneous tumor so the fiber that collects fluorescence can be in contact with the underlying tumor as well as the adjacent skin (Sheng *et al.*, 2004).

PS biodistribution

In experimental animals it has sometimes been possible to establish the overall pattern of distribution in the different organs after intravenous injection of the PS. A study (Bellnier *et al.*, 1989) using radioisotope labeled Photofrin in mice with subcutaneous fibrosarcoma tumors that were sacrificed 24h later found highest concentrations in liver, adrenal glands, and urinary bladder. Next was pancreas, kidney, spleen, and these organs were higher than stomach, bone, lung, and heart. Muscle concentration was low and brain was lowest. Only skeletal muscle, brain, and skin located distant to the tumor had peak concentrations lower than tumor tissue; the skin overlying the tumors showed concentrations not significantly different from tumor. The higher molecular weight components of Photofrin were partially retained in the liver and spleen at 75 days after injection.

In most cases where organ biodistribution data have been reported for small animals such as mice and rats, the highest concentration of PS has been found in the liver (Bertoloni *et al.*, 1990; Bhargava *et al.*, 2012). Chan *et al.* studied a set of sulfonated phthalocyanines found that the accumulation in liver was inversely proportional to the degree of sulfonation and hence to the overall lipophilicity of the PS molecules (Bhat *et al.*, 2005). The liver is known to have a highly permeable blood supply with fenestrated endothelium that contains pores that allow molecules to pass easily out of the blood vessels. This porous vasculature is required by the role of the liver in detoxifying the body of extraneous molecules (particularly organic molecules such as PS). These molecules are then excreted into the bile via the gall bladder in a similar fashion to the production of bile acids from cholesterol. The bile is routed into the duodenum where it is possible for unchanged PS to be absorbed into the circulation a second time from the small intestine (a process known as entero-hepatic recycling) as well as being excreted via the feces. It is known that soon after injection, large amounts of PS can accumulate in the lungs. Lung accumulation has been reported (Brun *et al.*, 2004) as the mode of dose-limiting dark toxicity when the PS injected doses were increased eventually leading to lung hemorrhage and acute interstitial pneumonia after injection of a high dose of 80 mg/kg of Pc4 into mice. The explanation is probably that large injected doses of PS can aggregate in the blood vessels and the particles so formed can easily collect in the fine capillary network of the lungs.

The amount of PS that accumulates in the spleen seems to vary widely with the structure of the PS (overall charge and hydrophobicity). Woodburn *et al.* (1992) studied a range of porphyrins with varying octanol/water partition coefficients and found the accumulation in the spleen varied the most compared to other organs. Egorin *et al.* (1999) compared organ distribution of Pc4 administered by IV injection of the same dose (10 mg/kg) dissolved in several solvents and found that the accumulation in the spleen was the most variable.

The kidney and bladder frequently accumulate high amounts of PS, despite the clearance route being almost exclusively via liver and bile (Richter *et al.*, 1990) rather than the kidneys and urine. The digestive organs (stomach, large and small intestines) seem to take up middling amounts of PS (i.e. less than liver but more than muscle) (Schuitmaker *et al.*, 1993). The skin has not been found to accumulate high amounts of PS in experimental animals, which might be considered somewhat surprising in view of the fact, that skin photosensitivity due to PS accumulation in patients' skin is the main cause of PDT-related side-effects. The lowest concentrations of PS are generally found in organs such as heart, skeletal muscle, bone, eye and brain. These are organs that are known to have a relatively impermeable blood supply. The blood-brain barrier serves to exclude PS from the parenchyma of the brain, while the fact that the blood-brain barrier is frequently breached by the growth of brain tumors is probably responsible for the very large (over 100) tumor-to-normal brain ratios reported for some PS (Boyle and Dolphin, 1996).

Since the original observation of the tumor localizing ability of hematoporphyrin derivative (HPD), many workers have investigated the underlying mechanism of this effect whereby PS preferentially localize in tumors, and in other specific organs and anatomical locations (Hamblin and Newman, 1994; Jori, 1989; Larroque *et al.*, 1996). The precise definition of "tumor to normal tissue ratio" has also been subject to debate. Some investigators working with subcutaneous tumors in experimental animals use the ratio between the tumor and peritumoral muscle or skin, while others use the ratio between the tumor to distant muscle and skin. Furthermore, there has been much effort made to determine which molecular features in the chemical structures of the PS are optimal for maximizing the selectivity for the tumor over normal tissue and organs. This has proved quite complicated because the pharmacokinetics of different PS can vary dramatically. For instance, one PS can have its best tumor to normal tissue ratio at a relatively early time point after administration such as 3 h, while for another PS this time point can be as long as 7 days after injection. One of the notable properties of these tetrapyrrole molecules that are commonly employed as PS, that may be relevant to their tumor localizing ability, is their tendency to bind strongly to serum proteins and also to bind to each other (aggregation). This high tendency to bind means that most PS when injected into the bloodstream behave as macromolecules rather than as small molecules, either because they are more or less firmly bound to large protein molecules or because they have formed intermolecular aggregates of similar size. Many workers have reported (Kessel and Poretz, 2000; Kongshaug *et al.*, 1989; Maziere *et al.*, 1990) on the distribution of PS between the various classes of serum proteins when mixed with serum (either human or animal) *in vitro*. These serum proteins are usually divided into four classes: (a) albumin and other heavy proteins; (b) high density lipoprotein (HDL); (c) low density lipoprotein (LDL); and (d) very low density lipoprotein (VLDL). However even this study has been complicated by the fact that the most lipophilic PS are insoluble in aqueous media and need to be delivered in a solvent mixture which may alter the serum protein distribution of the PS. It has been argued that PS that preferentially bind to LDL are better tumor localizers (see below) (Jori and Reddi, 1993) but this is by no means always the case (Korbelik, 1992).

It is useful to make a distinction between selective accumulation and selective retention. The tumor localizing ability of the PS with the faster pharmacokinetics is probably due to selective accumulation in the tumor, while the localization of PS with slower acting pharmacokinetics is more likely due to selective retention. In the selective accumulation model it is thought that the increased vascular permeability to macromolecules typical of tumor neovasculature is chiefly responsible for the preferential extravasation of the PS. These quick-acting PS frequently bind to albumin, which is of ideal size and Stokes radius to pass through the "pores" in the endothelium of the tumor micro-vessels (Yuan *et al.*, 1993). The selective retention model where PS can be retained in tumors, while they are eliminated from surrounding normal tissue and organs, has been the subject of much speculation. As mentioned above, a popular theory maintains that the binding of the PS to LDL is of major importance (Jori and Reddi, 1993). According to this theory, it is proposed that cancer cells over-express the LDL (apoB/E) receptor. Up-regulation of the expression of LDL receptors is one strategy that rapidly growing malignant cells have developed to obtain sufficient cholesterol that the tumor cells need for the biosynthesis of lipids required due to the rapid turnover of their cellular membranes. There is experimental evidence both for and against this LDL receptor theory (Allison *et al.*, 1994; Korbelik, 1992). Other theories have been proposed to account for the selective retention of PS in tumor tissue. One is that tumors are characterized by poorly

developed lymphatic drainage, and that macromolecules, which extravasate from the hyperpermeable tumor neovasculature, are retained in the extravascular space (Buytaert *et al.*, 2006b). This theory has been termed the well known “enhanced permeability and retention” (EPR) effect (Maeda *et al.*, 2016). Another theory is attributed to macrophages, which are phagocytic cells which infiltrate solid tumors to varying extents (Blanco *et al.*, 2015). These tumor-associated macrophages (TAMs) have been shown to accumulate up to thirteen times the amount of some PS compared to the cancer cells themselves (Buytaert *et al.*, 2007). The explanation for this preferential uptake by TAMs has been proposed to be due to either the phagocytosis of aggregates of PS (Canti *et al.*, 1994), or to the preferential uptake by TAMs of lipoproteins which have been subtly altered by the binding of porphyrins (Blanco *et al.*, 2015). Another theory proposes that the low pH commonly found in tumors (due to the Warburg effect in which the metabolism changes from oxidative phosphorylation to glycolysis, and produces large amounts of lactic acid) has the effect of trapping some of the anionic PS, which are normally ionized at normal physiological pH. These PS then become neutrally charged at low pH and hence more lipophilic, when they encounter the acidic pH in the tumor environment (Pottier and Kennedy, 1990). Yet another proposed mechanism is the selective accumulation of PS in tumors is related to the propensity of tumors to accumulate lipid droplets which may contain lipophilic molecules (Freitas, 1990). A final theory concerns the tendency of some tumors to have very high populations of tumor-associated macrophages, that may engulf particles of aggregated PS (Korbelik and Kros, 1995), or else take up PS that have bound to LDL, and then altered its behavior to be recognized by scavenger receptors (Hamblin and Newman, 1994).

Direct destruction of tumors by PDT

Many of the studies relating to this topic have been concerned with attempts to distinguish between direct tumor cell killing *in vivo* as described in the previous chapter, and indirect tumor cell killing caused by the vascular effects of PDT (see later).

Some studies have investigated an experimental model in which tumors in mice that had been treated with a potentially curative dose of PDT *in vivo* were removed from the mice, and then dissociated into a suspension of individual tumor cells. These tumor cells were still able to form colonies in a clonogenic assay if the tumors were removed immediately from the host after PDT (Henderson and Fingar, 1989; Henderson *et al.*, 1985). However when these tumors were left in the host animal for increasing lengths of time, a progressive loss in clonogenicity of the dissociated tumor cells was observed. These times corresponded to the emergence of PDT-induced tumor hypoxia as determined radiologically. These studies suggested a central role for vascular damage in governing the tumor response to PDT in mouse models.

Anti-vascular effect of PDT

Photodynamic alteration of tissue microcirculation was first reported in 1963 (Castellani *et al.*, 1963). A study by Star *et al.* (1986) utilized a window chamber in rats bearing an implanted mammary tumor, to make direct observations of the microcirculation of the tumor and the adjacent normal tissue before, during, and at various times after PDT mediated by HPD. An initial slowing down of blood flow and vasoconstriction of the tumor vessels was followed by heterogeneous responses including eventual complete cessation of blood flow, hemorrhage, and in some larger vessels, the formation of platelet aggregates. Other workers have histologically examined tissues removed from animal models that had been treated with PDT such as subcutaneous urothelial tumors and normal rat jejunum and reported a range of vascular responses including disruption of blood flow, breakdown of the blood brain barrier in the normal brain of mice, and endothelial cell damage in subcutaneous tumors and normal tissue (Bhuvaneswari *et al.*, 2009; Tseng *et al.*, 1988). Many reports cited above directly implicate the endothelium as a primary target for PDT *in vivo*; this stimulated research into the relative sensitivity of endothelial cells to PDT and the responses of endothelial cells that could initiate the various phenomena at the vessel level. Gomer *et al.* (1988) showed that bovine endothelial cells were significantly more sensitive to Photofrin-mediated PDT than smooth muscle cells or fibroblasts from the same species. This increased sensitivity to PDT, measured by clonogenic assay, was not a result of increased Photofrin accumulation. Sensitivity to HPD-mediated PDT of bovine aorta endothelial cells and human colon adenocarcinoma cells was investigated by West *et al.* (1990). Exponentially growing endothelial cells were significantly more sensitive than tumor cells with a similar rate of proliferation, and the difference in sensitivity was accompanied by greater PS accumulation in the endothelial cells.

Intravital microscopy of the rat cremaster muscle showed that Photofrin-PDT caused vessel constriction with an increase in vessel permeability and leukocyte adhesion was observed (Fingar *et al.*, 1992). The cyclooxygenase inhibitor indomethacin was able to inhibit the vessel constriction and reduce the increase in vascular permeability, implicating the involvement of the metabolites of cyclooxygenase called eicosanoids (such as thromboxane or prostacyclin). An increase in vascular permeability, thrombus formation and blood flow reduction were observed in animals treated with verteporfin-PDT in a dose- and time-dependent manner (Debefe *et al.*, 2010; Fingar *et al.*, 1999; He *et al.*, 2008). Blood vessels with lower flow rates were more sensitive to verteporfin-PDT-induced vascular shutdown than vessels with a higher flow rate. In agreement with light and electron microscopic studies, intravital fluorescence microscopic imaging demonstrated in live animals that verteporfin-PDT decreased endothelial cell viability and caused platelet aggregation (Khurana *et al.*, 2008). Rapid shutdown of tumor blood flow by formation of blood clots was also found after PDT with Tookad and MV6401, which was also confirmed by histological assessment (Dolmans *et al.*, 2002; Madar-Balakirski *et al.*, 2010). Many optical imaging studies have led to the conclusion that PDT is essentially a vascular disrupting therapy.

Immune stimulation effect of PDT: Innate immunity

PDT frequently provokes a strong acute inflammatory reaction in the targeted site, and this can often be observed as a fairly rapid induction of localized edema (Dougherty *et al.*, 1998). This reaction is a consequence of PDT-induced oxidative stress. Thus, PDT can be ranked among cancer therapies (including cryotherapy, hyperthermia, and focused ultrasound ablation) that all produce a chemical or physical destruction of tumor tissue that is perceived by the host as localized acute trauma. This tissue damage prompts the host to launch protective actions designed by evolution to react against threats to tissue integrity and to try to restore homeostasis at the affected site (Korbelik, 2006). The acute inflammatory response is the principal process engaged in this context. Its main task is containing the disruption of homeostasis, ensuring removal of damaged cells, and to protect against possible invasion of pathogenic microorganisms that may gain entry to the body as a result of a traumatic breach in external barriers. The inflammatory response also contributes to the local healing process with restoration of normal tissue function. The inflammation elicited by PDT is orchestrated by the innate immune system (Korbelik, 2006). The principal cells involved in this process consist of neutrophils, monocyte/macrophages, dendritic cells and mast cells. The recognition systems of the innate immune system are based upon a wide array of pattern-recognition receptors (PRRs), which are responsible for detecting the presence of tissue damage revealed to its sensors as the appearance of “altered-self” (Korbelik, 2006). PDT appears particularly effective in generating rapidly an abundance of alarm/danger signals, also called damage-associated molecular patterns (DAMPs) at the treated site that can be detected by the innate immune cells (Korbelik, 2006). Many DAMPs are nuclear or cytosolic proteins, or even small molecules that are normally safely contained inside healthy cells. When released outside from damaged or necrotic cells, or exposed on the surface of the cell following damage, they can encounter an oxidizing environment, which results in their changes in their conformation or chemical structure (Garg *et al.*, 2015). DNA can be released outside the nucleus from necrotic cells, and becomes a DAMP (Magna and Pisetsky, 2016). Other DAMPs (Garg *et al.*, 2015) include heat-shock proteins, high mobility group box protein 1 (HMGB1), hyaluronan fragments, extracellular ATP, uric acid, heparin sulfate and S100 molecules (members of a family of calcium modulated proteins).

Dendritic cells (DCs) are professional antigen presenting cells that have been described as the “orchestrators” of the immune response (Bhargava *et al.*, 2012). DCs express many receptors that specifically recognize DAMPs. Since PDT of tumor cells causes both cell death and cell stress (Dougherty *et al.*, 1998; Henderson and Gollnick, 2003; Oleinick and Evans, 1998) it is hypothesized that the activation of DCs by PDT-treated cells is the result of recognition of DAMPs released/secreted/exposed by PDT from dying cells (Gollnick *et al.*, 2006; Korbelik *et al.*, 2005, 2007). HSP70 is a well-characterized DAMP that interacts with the danger signal receptors, TLRs (Toll-like receptors) 2 and 4 (Vabulas *et al.*, 2002) and is induced by PDT (Gomer *et al.*, 1996). The level of expression of HSP70 in PDT-treated tumor cells appears to correlate with an ability to stimulate DC maturation (Gollnick *et al.*, 2004) and initiation of inflammation (Korbelik *et al.*, 2005; Stott and Korbelik, 2007).

The onset of PDT-induced inflammation is marked by dramatic changes in the tumor vasculature that becomes permeable to serum proteins and expresses adhesion molecules that circulating inflammatory cells can recognize and to which they can adhere (Korbelik, 2006). This process is responsible for the well-known “rolling” behavior of neutrophils and other leukocytes. The inflammatory process is predominantly initiated by signals originating from photooxidative damage produced in perivascular regions of the tumor with chemotactic gradients reaching out from the damaged endothelium. The inflammatory cells, initially consisting of neutrophils, which are then followed by mast cells and monocytes/macrophages, rapidly and massively invade tumors after PDT (Fig. 7) (Dougherty *et al.*, 1998; Krosi *et al.*, 1995). The primary task of these infiltrating cells is to neutralize the source of DAMPs by removing debris containing injured and dead cells and oxidatively damaged tissue components. Damage and dysfunction of PDT-treated tumor vasculature frequently results in vascular occlusion that serves to “seal off” the damaged tumor tissue until it is removed by invading phagocytic cells (Korbelik, 2006). Depletion of neutrophils or inhibition of their activity after PDT was shown to diminish the therapeutic effect (de Vree *et al.*, 1997; Korbelik and Cecic, 1999, 2003; Kousis *et al.*, 2007). Among the cytokines involved in the regulation of the inflammatory process, the most important ones for the PDT response are IL-1 β and IL-6 (Gollnick *et al.*, 2003; Sun *et al.*, 2002). Blocking the function of various adhesion molecules was also shown to inhibit the PDT response (Gollnick *et al.*, 2003; Sun *et al.*, 2002). On the other hand, blocking anti-inflammatory cytokines such as IL-10 and TGF- β can significantly improve the cure rates after PDT (Korbelik, 2006).

Fig. 7 illustrates the stimulation of immune response after PDT.

Immune stimulation effect of PDT: Adaptive immunity

A wide range of pre-clinical animal studies and even some clinical studies have demonstrated that PDT can influence the adaptive immune response in disparate ways. Some PDT regimens result in potentiation of adaptive immunity, while others lead to immunosuppression. The precise reasons why PDT can lead to potentiation vs. suppression are unclear; however it appears as though the effect of PDT on the immune system is dependent upon the treatment regimen, as well as the area treated and the precise PS type (Hunt and Levy, 1998; Kousis *et al.*, 2007). PDT induced immune suppression is largely confined to cutaneous and transdermal PDT regimens involving large surface areas (Hunt and Levy, 1998; Yusuf *et al.*, 2008).

Broadly speaking PDT efficacy appears to be dependent upon the induction of adaptive anti-tumor immunity. Long-term tumor response and cures are diminished or absent in immunocompromised mice such as nude mice or SCID mice (Korbelik and Cecic, 1999; Korbelik *et al.*, 1996). Reconstitution of these animals by injecting bone marrow or T cells isolated from immunocompetent (normal) mice can result in increased PDT efficacy. Canti *et al.* (1994) were the first to show PDT-induced immune stimulation, demonstrating that cells isolated from tumor-draining lymph nodes of PDT-treated mice were able to confer tumor

Fig. 7 Stimulation of immune response after PDT of tumors.

resistance when injected into naïve mice. Subsequent studies demonstrated that PDT directed against murine tumors resulted in the generation of immune memory such as rejection of a tumor rechallenge in mice that had obtained a long-term cure after PDT (Korbelik and Dougherty, 1999).

In order for the adaptive immune response produced by PDT to be highly effective, it appears that the tumor cell line employed should express what has been called a “tumor rejection antigen”. This has been demonstrated by testing PDT of syngeneic mouse tumors that have been engineered to express a model tumor antigen in immunocompetent mice. One of these model antigens was the bacterial protein beta-galactosidase (b-gal) (Mroz *et al.*, 2010). Although the b-gal tumors grew as rapidly as their wild-type counterparts, there was 100% long-term cures after BPD-mediated PDT with the b-gal tumors but no long-term cures with the wild-type tumors. The strength of the anti-tumor immune response was demonstrated by the fact that if mice had two b-gal tumors (one in each leg) and only one was treated with PDT, the contralateral untreated tumor underwent spontaneous regression in 70% of the mice. A similar result was seen in mice bearing the mastocytoma P815 that is well known to express the naturally-occurring tumor rejection antigen called P1A (Mroz *et al.*, 2013). The CD8 cytotoxic T-cells can recognize specific peptide epitopes derived from the amino acid sequence of the tumor antigen.

MHC-I is critical for allowing the CD8⁺ T cells to recognize the tumor antigen, and tumors that lack MHC-I are resistant to cell-mediated anti-tumor immune reactions (Maeurer *et al.*, 1996). Since MHC1 expression and expression of tumor associated antigens (such as P1A) are both susceptible to down-regulation by epigenetic silencing, an epigenetic reversal agent (the demethylating compound, 5-aza-2'-deoxycytidine) could potentiate the induction of anti-tumor immunity and increase cures in several mouse tumor models (Wachowska *et al.*, 2014).

The mechanism whereby PDT enhances anti-tumor immunity has been examined for the past several decades. PDT activates both humoral and cell-mediated anti-tumor immunity, although the importance of the humoral response (antibodies) is at present unclear. PDT efficacy in mice and humans is reduced in the absence of CD8⁺ T cell activation and/or tumor infiltration (Abdel-Hady *et al.*, 2001; Kabingu *et al.*, 2007; Korbelik and Cecic, 1999). Therefore most mechanistic studies have focused on the means by which PDT potentiates CD8⁺ T cell activation. It is clear that induction of anti-tumor immunity following PDT is dependent upon induction of inflammation (Henderson *et al.*, 2004). PDT-induced acute local and systemic inflammation is postulated to culminate in the maturation and activation of dendritic cells (DCs). Mature DCs are critical for activation of tumor specific CD8⁺ T cells and induction of anti-tumor immunity (Reis e Sousa, 2004). DCs are activated in response to PDT (Gollnick *et al.*, 2003) and migrate to tumor draining lymph nodes where they present the antigens they have taken up from damaged tumor cells to naïve T cells in the so-called “immune synapse” (Benvenuti, 2016). The T-cells in the lymph node become activated and proliferate dramatically and a “flood” of tumor-specific CTLs is released into the blood stream where they can search for other tumors cells to attack and destroy (Gollnick *et al.*, 2003; Sur *et al.*, 2008). Generation of CD8⁺ effector and memory T cells is frequently, but not always dependent upon the presence and activation of CD4⁺ T cells (Castellino and Germain, 2006). PDT induced anti-tumor immunity may (Korbelik and Cecic, 1999) or may not depend on CD4⁺ T cells (Kabingu *et al.*, 2007) and may be augmented by natural killer (NK) cells (Kabingu *et al.*, 2007).

PDT-mediated enhancement of anti-tumor immunity is believed to be due, at least in part, to stimulation of DCs by dead and dying tumor cells, suggesting that in vitro PDT-treated tumor cells may act as effective anti-tumor vaccines (Gollnick *et al.*, 2002).

This hypothesis has been proven by several studies using a wide variety of different PS and tumor models in both preventative and therapeutic settings (Gollnick *et al.*, 2002; Korbelik and Cecic, 2003; Korbelik *et al.*, 2009; Korbelik and Sun, 2006).

Mechanistic studies showed that incubation of immature DCs with PDT-treated tumor cells leads to enhanced DC maturation, activation and increased ability to stimulate T cells (Gollnick *et al.*, 2002; Jalili *et al.*, 2004). Furthermore, opsonization of PDT-treated tumor cells by complement proteins increases the efficacy of PDT-generated vaccines (Korbelik and Sun, 2006).

Induction of anti-tumor immune response after PDT

How does an effective anti-tumor immune response triggered after PDT manifest itself? This depends on whether pre-clinical animal tumor models (most often mice or rats) are being studied, or whether clinical studies are being considered. In an ideal scenario the immune stimulation would be strong enough for an animal or a patient with metastatic cancer who had the primary tumor treated with PDT, and then to have the distant untreated metastases regress over time as the host T-cells recognize specific tumor antigens and then attack and destroy their cognate target cells.

The implications of PDT-induced anti-tumor immunity and efficacious PDT-generated vaccines are significant and provide an exciting possibility for using PDT in the treatment of metastatic disease and as an adjuvant in combination with other cancer modalities. Several pre-clinical studies demonstrated that PDT is able to control the growth of tumors present outside the treatment field (Gomer *et al.*, 1987; Kabingu *et al.*, 2007) although others have failed to demonstrate control of distant disease following PDT (van Duijnhoven *et al.*, 2003).

This ideal scenario was demonstrated (Mroz *et al.*, 2010) in a mouse model where a BALB/c syngeneic colon carcinoma called CT26 was implanted subcutaneously in the leg and treated by a vascular PDT regimen mediated by liposomal verteporfin and 690 nm light. Although an apparently complete local response was achieved by application of PDT, the mice all suffered a local recurrence of the tumor in the leg and were sacrificed within a few weeks. By contrast, when the CT26 tumor was engineered to express a model tumor antigen (β -galactosidase) to form a tumor cell line called CT26. CL25, the tumors grew in the mice the same as CT26 wild-type. However CT26. CL25 tumors gave 100% permanent cures after PDT, and the cured mice were resistant to a rechallenge with CT26. CL25 tumor cells (but not to CT26 cells). When mice with two bilateral CT26. CL25 tumors (1 in each leg) had only the right-leg tumor treated with PDT, the distant untreated left-leg tumor spontaneously regressed over a period of several weeks. In about 70% the regression of both tumors was permanent, while in the remaining 30% of mice where the untreated CT26. CL25 tumor was observed to recur, it was found that the recurrent tumor has lost expression of the β -galactosidase antigen. Loss of antigen expression is a recognized route by which highly plastic tumors can evade the host immune response.

The efficacy of clinical PDT also appears to depend on induction of anti-tumor immunity. Patients with vulval intraepithelial neoplasia (VIN) who did not respond to ALA-PDT were more likely to have tumors that lacked major histocompatibility complex class I molecules (MHC-I) than patients who responded to ALA-PDT (Abdel-Hady *et al.*, 2001). VIN patients who responded to PDT had increased CD8⁺ T cell infiltration into the treated tumors as compared to non-responders. In other clinical studies patients who were treated with PDT for actinic keratoses and Bowen's disease were divided into immunocompetent and immunosuppressed sub-groups. Both sub-groups had similar initial response rates to PDT, but immunosuppressed patients had less long-term responses and were more likely to suffer appearance of new lesions (Dragieva *et al.*, 2004). In a recent clinical study, PDT of multifocal angiosarcoma of the head and neck resulted in increased immune cell infiltration into distant untreated tumors that was accompanied by tumor regression (Thong *et al.*, 2007, 2008). PDT was also shown to be an effective surgical adjuvant in non-small-cell lung cancer patients with pleural spread (Friedberg *et al.*, 2004). Recent reports have shown that clinical anti-tumor PDT also increases anti-tumor immunity. PDT of basal cell carcinoma (BCC) increased immune cell reactivity against a BCC-associated antigen (Kabingu *et al.*, 2009).

Photobiomodulation – The Healer

Light alone when it is delivered at a relatively low irradiance and fluence is called low level light (laser) therapy (LLLT) and has almost the complete opposite effect to PDT. The internationally accepted terminology for LLLT has recently been changed to "photobiomodulation" (PBM) therapy, due to widespread uncertainties about just exactly what parameters constituted "low level" (Anders *et al.*, 2015). LLLT (or PBM) was discovered in a rather serendipitous manner by Endre Mester in the 1960s. The discovery of the laser in 1960 by Theodore Maiman, had been recognized as a landmark in modern physics, and garnered an enormous amount of international attention (Maiman, 1960). In 1961 Leon Goldman started to experiment with the effect that these newly discovered laser beams had on the skin (Goldman *et al.*, 1963), and asked whether they could be used to perform "bloodless surgery". In the early 1960s Paul McGuff in Boston made medical history by using a laser beam to vaporize human cancer cells that had been transplanted into a hamster (McGuff *et al.*, 1965). In 1965 Mester started laser research in Hungary and tried to repeat McGuff's experiments by implanting tumor cells beneath the skin of laboratory rats and exposing them to the beam from a customized ruby laser. However the tumor cells were not destroyed by doses of what was presumed to be high-power laser energy, but instead, the skin incisions that had been made to implant the cancer cells appeared to heal faster in laser-treated animals, compared to incisions of control animals that were not treated with light (Mester *et al.*, 1968b). Moreover the regrowth of hair on the depilated rat skin, was observed to be faster after exposure to his ruby laser (Mester *et al.*, 1968c). After being initially puzzled by these contradictory findings, he realized that the output power of his custom-designed ruby laser was much weaker than he originally thought it to be, and instead of being photo-ablative against the tumor tissue, the low-power light stimulated the skin to

Fig. 8 Wide range of medical indications susceptible to treatment by PBM.

heal faster and caused the hair to regrow. Since those early days the range of medical indications that can be treated by LLLT or PBM has continued to expand almost exponentially as shown in [Fig. 8](#).

Mechanisms of Action

The first law of photobiology lays down that in order for a photon to have a biological effect it has to be absorbed by a specific photoacceptor molecule also known as a "chromophore". The leading hypothesis is that light is absorbed by chromophores in the mitochondria such as cytochrome c oxidase leading to production of more ATP and activation of a host of cell signaling pathways leading to gene transcription (Chen *et al.*, 2009). A secondary hypothesis is that longer wavelength light (in the infrared region) is absorbed by water in sensitive cellular locations such as ion channels (see [Fig. 9](#) for a graphical illustration). Instead of killing cells (as is the case with PDT) PBM stimulates cellular proliferation and prevents cells from dying (Huang *et al.*, 2009). The medical applications of PBM range from serious diseases such as stroke, heart attack, spinal cord injury, traumatic brain injury to less serious indications such as wound healing, reduction of pain and inflammation and depression (Hashmi *et al.*, 2010).

Cytochrome C oxidase

Cytochrome C oxidase (Cox) is the terminal enzyme of the electron transport chain, mediating the electron transfer from cytochrome c to molecular oxygen. Several lines of evidence show that Cox acts as a photoacceptor and transducer of photsignals in the red and near-infrared regions of the light spectrum (Anneroth *et al.*, 1988). It seems that PBM increases the availability of electrons for the reduction of molecular oxygen in the catalytic center of Cox, increasing the mitochondrial membrane potential (MMP) and the levels of ATP, cAMP and ROS as well (Barcia, 2012).

PBM increases the activity of complexes I, II, III, IV and succinate dehydrogenase in the electron transfer chain. Cox is known as complex IV and, as mentioned before, appears to be the primary photoacceptor. This assumption is supported by the increased oxygen consumption during low-level light irradiation (the majority of the oxygen consumption of a cell occurs at complex IV in the mitochondria), and by the fact that sodium azide, a Cox inhibitor, prevents the beneficial effect of PBM. Besides ATP and cAMP, nitric oxide (NO) level is increased, either by release from metal complexes in Cox (Cox has two heme and two copper centers) or by up-regulation of the activity of Cox as a nitrite reductase (Barolet *et al.*, 2009).

Retrograde mitochondrial signaling

One of the most accepted mechanisms for light-cell interaction was proposed by Karu (Barrett and Gonzalez-Lima, 2013), referring to the retrograde mitochondrial signaling that occurs with light activation in the visible and infrared range. According to Karu, the first step is the absorption of a photon with energy $h(\nu)$ by the chromophore Cox. This interaction increases

Fig. 9 Main mechanisms of action of PBM at a cellular level.

mitochondrial membrane potential ($\Delta\Psi_m$), causing an increase in the synthesis of ATP and changes in the concentrations of reactive oxygen species (ROS), Ca^{2+} and NO. Furthermore, there is a communication between mitochondria and the nucleus, driven by changes in the mitochondria ultrastructure, i.e. changes in the fission-fusion homeostasis in a dynamic mitochondrial network. The alteration in the mitochondrial ultrastructure induces changes in ATP synthesis, in the intracellular redox potential, in the pH and in cyclic adenosine monophosphate (cAMP) levels. Activator protein-1 (AP1) and NF- κ B have their activities altered by changes in membrane permeability and ion flux at the cell membrane. Some complementary routes were also suggested by Karu, such as the direct upregulation of some genes (Bellnier *et al.*, 1997).

Light/heat sensitive ion channels

The most well-known ion channels that can be directly gated by light are the channelrhodopsins (ChRs), which are seven-transmembrane-domain proteins that can be naturally found in algae providing them with light perception. Once activated by light, these cation channels open and depolarize the membrane. They are currently being applied in neuroscientific research in the new discipline of optogenetics (Bellnier *et al.*, 1989).

However members of another broad group of ion-channels are now known to be more or less light sensitive (Benvenuti, 2016). These channels are called “transient receptor potential” (TRP) channels as they were first discovered in a *Drosophila* mutant (Benvenuti, 2016). TRP channels are responsible for vision in insects. There are now known to be at least 50 different TRP isoforms distributed amongst seven subfamilies (Bernstein, 2005). These are called the TRPC (‘Canonical’) subfamily, the TRPV (‘Vanilloid’), the TRPM (‘Melastatin’), the TRPP (‘Polycystin’), the TRPML (‘Mucolipin’), the TRPA (‘Ankyrin’) and the TRPN (‘NOMPC’) subfamilies. A wide range of stimuli modulate the activity of different TRP such as light, heat, cold, sound, noxious chemicals, mechanical forces, hormones, neurotransmitters, spices, and voltage. TRP are calcium channels modulated by phosphoinositides (Bertoloni *et al.*, 1990).

The evidence that light mediated activation of TRP is responsible for some of the mechanisms of action of PBM is somewhat sparse at present, but is slowly mounting.

Mast cells are known to accumulate at the site of skin wounds, and there is some degree of evidence suggesting that these cells play a role in the biological effects of laser irradiation on promoting wound healing. Yang and co-workers demonstrated that after laser irradiation (532 nm), the intracellular $[\text{Ca}^{2+}]$ was increased and, as a consequence, there was a release of histamine. If the TRPV4 inhibitor, ruthenium red, was used, the histamine release was blocked, indicating the central role of these channels in promoting histamine-dependent wound healing after laser irradiation (Bhargava *et al.*, 2012).

It seems that TRPV1 ion channels are involved in the degranulation of mast cells and laser-induced mast cell activation. It was demonstrated that capsaicin, temperatures above 42°C and acidic pH could induce the expression of TRPV1 in oocytes, and these ion channels can be activated by green light (532 nm) in a power-dependent manner, although blue and red light were not able to activate them (Bhat *et al.*, 2005). Infrared light (2780 nm) attenuates TRPV1 activation by capsaicin in cultured neurons, decreasing the generation of pain stimuli. TRPV4 is also attenuated by laser light, but the antinociceptive effect was less intense, therefore the antinociception in this model is mainly dependent on TRPV1 inhibition (Bhuvanawari

et al., 2009) The stimulation of neurons with pulsed infrared light (1875 nm) is able to generate laser-evoked neuronal voltage variations and, in this case, TRPV4 channels were demonstrated to be the primary effectors of the chain reaction activated by the laser (Bisht *et al.*, 1994).

Flavins

Rachel Lubart showed that flavins were able to absorb light in the 400–500 nm wavelength range (Eichler *et al.*, 2005). This led to the production of ROS inside cells. Since ROS appear to be produced by different wavelengths of light that target different chromophores, it is probably a general mechanism involved in PBM effects (Lavi *et al.*, 2010).

Direct cell-free light-mediated effects on molecules

There have been some scattered reports that light can have effects on some important molecules in cell free systems (in addition to the established effect on Cox). The latent form of transforming growth factor beta has been reported to be activated by light exposure (Bisht *et al.*, 1999). Superoxide dismutase (Cu,Zn) from bovine erythrocytes that had been inactivated by exposure to pH 5.9 was reactivated by exposure to He-Ne laser light (632.7 nm) (Bjordan *et al.*, 2003). The same treatment also reactivated the heme-containing catalase. Amat *et al.* showed that irradiation of ATP in solution by 655 nm or 830 nm light appeared to produce changes in its enzyme reactivity, fluorescence and Mg²⁺ binding capacity (Bjornsti and Houghton, 2004). However other workers were unable to repeat this somewhat surprising result (Blanco *et al.*, 2015).

PBM for Healing of Wounds and Tissue Damage

The first demonstration the clinical effectiveness of PBM was in non-healing wounds in patients in the early 1970s (Mester *et al.*, 1972). Since then many authors have published studies in both animal models and clinical trials showing positive effects. Our study in excisional wounds in mice showed that certain wavelengths (635 nm and 810 nm) were better than others and moreover there was a biphasic dose response with an optimum fluence of 2 J/cm² (Demidova-Rice *et al.*, 2007).

Wound healing was one of the first applications of PBM, when HeNe lasers were used by Mester *et al.* to treat skin ulcers (Mester *et al.*, 1971, 1972, 1976, 1968b). PBM is believed to affect all three phases of wound healing (Thomas *et al.*, 1995): the inflammatory phase, in which immune cells migrate to the wound, the proliferative phase, which results in increased production of fibroblasts and macrophages, and the remodeling phase, in which collagen deposition occurs at the wound site and the extracellular matrix is rebuilt.

PBM is believed to promote wound healing by inducing the local release of cytokines, chemokines, and other biological response modifiers that reduce the time required for wound closure, and increase the mean breaking strength of the wound (Bisht *et al.*, 1999; Hawkins *et al.*, 2005; Meyers, 1990). Proponents of PBM speculate that this result is achieved by increasing the production and activity of fibroblasts and macrophages, improving the mobility of leukocytes, promoting collagen formation, and inducing neovascularization (Hawkins and Abrahamse, 2005; Loevschall and Arenholt-Bindslev, 1994; Medrado *et al.*, 2003; Noble *et al.*, 1992; Reddy *et al.*, 2001; Skinner *et al.*, 1996).

However, there is a lack of convincing clinical studies that either prove or disprove the efficacy of PBM in wound healing. The results that are currently available are conflicting and do not lead to any clear conclusions. For example, Abergel *et al.* found that the 632.8 nm HeNe laser did not have any effect on the cellular proliferation of fibroblasts, while the 904 nm GaAs laser actually lowered fibroblasts proliferation (Abergel *et al.*, 1987a). In contrast, other studies noted an increase in proliferation of human fibroblasts exposed to 904 nm GaAs lasers (Pereira *et al.*, 2002), rat myofibroblasts exposed to 670 nm GaAs lasers (Medrado *et al.*, 2003), and gingival fibroblasts exposed to diode lasers (670, 692, 780, and 786 nm) (Almeida-Lopes *et al.*, 2001). *In vivo* studies in both animal and human models show similar discrepancies. A study by Kana *et al.* claimed that treatment of open wounds in rats with HeNe and argon lasers resulted in faster wound closure (Kana *et al.*, 1981). Bisht *et al.* found a similar increase in granulation tissue and collagen expression in rats using the same treatment as Kana (Bisht *et al.*, 1994). However, Anneroth *et al.* failed to observe any beneficial effects after laser treatment in a comparable rat model (Anneroth *et al.*, 1988). In human studies, Schindl *et al.* reported that application of a HeNe laser was beneficial in promoting wound healing in 3 patients (Schindl *et al.*, 2000), whereas Lundeberg *et al.* found no statistically significant difference between leg ulcer patients treated with an HeNe laser and those treated with a placebo (Lundeberg and Malm, 1991).

The scarcity of well-designed clinical trials makes it difficult to assess the impact of PBM on wound healing. Our task is further complicated by the difficulty in comparing studies, due to the large number of factors involved. In addition to the multiple parameters that must be adjusted in order to apply PBM, such as the wavelength and power of the light, the effectiveness of the treatment also depends on many factors such as the location and nature of the wound, and the physiologic state of the patient. For example, impaired wound healing is one of the major chronic complications of diabetes (Goodson and Hunt, 1979; Raskin *et al.*, 1975), and is thought to result from various factors, including decreased collagen production and impaired functionality of fibroblasts, leukocytes, and endothelial cells (Goodson and Hunt, 1979; Spanheimer *et al.*, 1988). It has therefore been hypothesized that PBM could have beneficial effects in stimulating wound healing in diabetic patients (Schindl *et al.*, 1998, 2002; Yu *et al.*, 1997). Thus, in order to obtain a convincing verdict on the impact of PBM on wound healing, we will require several large, randomized, placebo controlled, and double blind trials that compare the effects of PBM on wounds that are as similar as possible. A greater understanding of the cellular and biochemical mechanisms of PBM would

also be useful in assessing these studies, as it would enable us to pinpoint exactly what criteria to use in determining the effectiveness of the therapy.

PBM for Pain and Inflammation

PBM can be used with great benefit in numerous inflammatory disorders such as arthritis, carpal tunnel syndrome, and tendinitis. We showed that 810-nm laser was very effective in a rat model of inflammatory arthritis caused by intra-articular injection of zymosan (Castano *et al.*, 2007). A sufficiently long illumination time was more important than total fluence or the irradiance in determining the benefit of the therapy.

There appears to be more firm evidence to support the success of PBM in alleviating pain and treating chronic joint disorders, than in healing wounds. A review of 16 randomized clinical trials including a total of 820 patients found that PBM reduces acute neck pain immediately after treatment, and up to 22 weeks after completion of treatment in patients with chronic neck pain (Chow *et al.*, 2009). PBM has also been shown to relieve pain due to cervical dentinal hypersensitivity (Sandford and Walsh, 1994), or from periodontal pain during orthodontic tooth movement (Wahl and Bastanier, 1991). A study of 88 randomized controlled trials indicated that PBM can significantly reduce pain and improve health in chronic joint disorders such as osteoarthritis, patellofemoral pain syndrome, and mechanical spine disorders (Bjordan *et al.*, 2003). However, the authors of the study urge caution in interpreting the results due to the wide range of patients, treatments, and trial designs involved.

PBM for Cosmetic and Esthetic Applications

Skin rejuvenation

PBM is a novel treatment option for non-thermal and non-ablative skin rejuvenation which has been shown to be effective for improving skin conditions such as wrinkles and skin laxity (Barolet *et al.*, 2009; Bhat *et al.*, 2005; Dierickx and Anderson, 2005; Russell *et al.*, 2005; Weiss *et al.*, 2004a,b). A wide range of different light sources have been used to deliver light for these treatments, particularly to the face, and some are shown in Fig. 10. PBM is a treatment modality that has been shown to provide increased rates of skin rejuvenation and wound healing with great efficacy, while also reducing post-operative pain, edema and several types of inflammation, making it highly desirable modality (Kim and Calderhead, 2011; R.G. *et al.*, 2008). Early studies by Abergel *et al.* and Yu *et al.* reported an increase in production of pro-collagen, collagen, basic fibroblast growth factors (bFGF) and proliferation of fibroblasts after exposure to low-energy laser irradiation in vitro and in vivo animal models (Abergel *et al.*, 1987b; Yu *et al.*, 1994). Use of light sources with wavelengths of 633 nm/830 nm is most common in cases of clinical application involving wound healing and skin rejuvenation. PBM is now used for the treatment of even chronic non-healing wounds through restoration of imbalances in collagenesis/collagenase and allows for rapid and enhanced wound healing in general (Kim and Calderhead, 2011). Lee *et al.* conducted a study to investigate the histological and ultrastructural alterations that followed a series of light treatments utilizing light emitting diodes (LEDs) with parameters of 830 nm, 55 mW/cm², 66 J/cm² and 633 nm, 105 mW/cm², 126 J/cm². They observed alteration in the levels of MMPs and tissue inhibitors of metalloproteinases (TIMPs)

Fig. 10 Selection of light sources used for PBMT of skin conditions.

(Lee *et al.*, 2007). The study also showed increased mRNA levels of interleukin-1 beta (IL-1 β), tumor necrosis factor alpha (TNF- α), intercellular adhesion molecule 1 (ICAM-1), and connexin 43 (C $\times$ 43) following LED phototherapy whereas IL-6 levels were decreased (Lee *et al.*, 2007). Subsequently the study also demonstrated a well-marked increase in the amount of collagen in the post-treatment specimens (Lee *et al.*, 2007). In fractional laser resurfacing it is thought that the deliberate development of microscopic photothermally-mediated wounds is responsible for the recruitment of pro-inflammatory cytokines IL-1 β and TNF- α *in order cause wound repair*. The generation of such a wound healing cascade thus contributes to new collagen synthesis (Lee *et al.*, 2007). PBM may also induce this wound healing process through athermal and atraumatic induction of a subclinical 'quasi-wound', even without any actual wounding created by thermal damage which can possibly cause complications as in some other laser treatments (Lee *et al.*, 2007). MMP activities are known to be inhibited by TIMPs, suggesting the possibility of other mechanisms for increased collagen synthesis through induction of TIMPs.

Collectively viewing these findings, they are suggestive of the idea that an increased production of IL-1 β and TNF- α might be responsible for induction of MMP activity as an early response to light treatment, which might possibly contribute to the removal of photodamaged collagen fragments in order to facilitate new collagen biosynthesis. Furthermore, as a consequence of the therapy there may be increased concentrations of TIMPs that most likely play a role in the protection of the newly synthesized collagen, from proteolytic degradation by MMPs (Lee *et al.*, 2007). Subsequently, heightened expression of C $\times$ 43 may possibly enhance cell-cell communication between dermal components, especially between fibroblasts, allowing for greater synchrony between cellular responses, following the effects of PBM in order to promote synthesis of new collagen in a greater area including even the regions that did not receive light irradiation (Lee *et al.*, 2007).

A clinical study conducted by Weiss *et al.* demonstrated the benefits of PBM over traditional thermal-based rejuvenation modalities. A group of 300 patients were administered PBM (590 nm, 0.10 J/cm²) alone, and another group of 600 patients received a combination of PBM with a thermal-based photorejuvenation procedure. Of the patients who received just the light treatment, 90% reported an observed softening of skin textures as well as a reduction in skin coarseness and fine lines that ranged from small alterations to significant changes (Weiss *et al.*, 2005b). It was observed that patients who received a form of PBM (n=152) reported a noticeable reduction in post-treatment erythema and an overall impression of increased efficacy versus patients that received treatment through a thermal photorejuvenation laser or light source lacking any sort of PBM photomodulation (Kucuk *et al.*, 2010; Weiss *et al.*, 2005b). Reduction in post-treatment erythema can most likely be attributed to the anti-inflammatory effects of PBM (Barolet *et al.*, 2009). Utilizing different pulse sequence parameters, a multicenter clinical trial was conducted, wherein 90 patients received 8 PBM treatments over 4 weeks (Geronemus *et al.*, 2003; McDaniel *et al.*, 2003; Weiss *et al.*, 2004a,b, 2005a). The study found good overall results with more than 90% of patients improving by at least one Fitzpatrick photoaging category and 65% of the patients displaying global improvement in facial texture, fine lines, background erythema and pigmentation with results peaking at 4 to 6 months following completion of the 8 treatments. A noticeable increase in papillary dermal collagen and reductions in MMP-1 were generally observed. A study conducted by Barolet *et al.* also proved to be consistent with the aforementioned studies. The study used a 3-D model of tissue-engineered Human Reconstructed Skin (HRS) to investigate the potential of PBM (660 nm, 50 mW/cm², 4 J/cm²) in collagen and MMP-1 modulation. The results showed up-regulation of collagen and down-regulation MMP-1 *in vitro* (Barolet *et al.*, 2009). A split-face, single-blinded clinical study was then carried out to assess the results of this light treatment on skin texture and appearance of individuals with aged/photoaged skin (Barolet *et al.*, 2009). Profilometry quantification (to measure wrinkles) demonstrated that more than 90% of individuals had a reduction in rhytid depth and surface roughness, and, 87% of the individuals reported that they have experienced a reduction in the Fitzpatrick wrinkling severity score following 12 PBM treatments (Barolet *et al.*, 2009).

PBM for hair regrowth

As mentioned above in the late 1960s, Endre Mester, a Hungarian physician, conducted a series of experiments to investigate the anti-cancer effect of lasers using a low-powered ruby laser (694 nm) on mice and much to his surprise, not only did laser exposure not cure cancer instead it seemed to enhance hair growth in the shaved area of the mice that had been set up for the original experiment (Mester *et al.*, 1968a). Quite recently, lasers have garnered much attention due to their remarkable ability to cause selective hair removal, however in some cases it was observed that lasers in fact produced undesired hair growth effects such as increase in hair density, color or coarseness or a combination of any of these, in areas of the skin that were treated for hair removal (Moreno-Arias *et al.*, 2002a,b; Vlachos and Kontoes, 2002; Wikramanayake *et al.*, 2012a). This phenomenon is known as 'paradoxical hypertrichosis' and its incidence varies from 0.6% to 10% (Wikramanayake *et al.*, 2012a). A group of researchers also observed that low-powered laser irradiation of small vellus hairs cause them to transform into larger terminal hairs, and thus termed this process as "terminalization" of vellus hair follicles (Bernstein, 2005; Bouzari and Firooz, 2006). Different mechanisms have been proposed by dermatologists (who did not not really believe in PBM) in an attempt to explain these effects of lasers on hair removal. In one particular study this ability was attributed to the fact that polycystic ovarian syndrome was present in 5 out of 49 females undergoing intense pulsed laser (IPL) laser treatment for facial hirsutism (Moreno-Arias *et al.*, 2002a). Another study suggested that despite the heat generating effects of laser treatments, the heat produced was not sufficient enough to induce total hair follicle thermolysis but, it may be sufficient to stimulate follicular stem cell proliferation and differentiation by increasing levels of heat shock proteins (HSPs) such as HSP27 which influence regulation of cell growth and differentiation (Wikramanayake *et al.*, 2012a).

In 2007, the FDA approved PBM as a possible treatment modality for hair loss (Wikramanayake *et al.*, 2012a). It is believed that non-thermal PBM can stimulate reentry of anagen hair follicles into the telogen stage, bringing about greater rates of proliferation

in active anagen follicles, can prevent development of premature catagen stage follicles and extend the duration of the anagen phase (Leavitt *et al.*, 2009; Wikramanayake *et al.*, 2012a).

In one study conducted by Yamazaki and colleagues, irradiated the backs of Sprague Dawley rats using a linearly polarized IR source, where an up-regulation of hepatocyte growth factor (HGF) and HGF activator expression was discovered (Miura *et al.*, 1999). Another study reported increases in temperature of the skin and improved blood flow around the stellate ganglion area, following treatment with PBM (Wajima *et al.*, 1996). The exact mechanism for the action of minoxidil in treating hair loss is not entirely understood, but it is known that minoxidil does contain nitric oxide (NO) which is an important cellular signaling molecule and vasodilator (Proctor, 1989) that is influential to a variety of physiological and pathological processes (Hou *et al.*, 1999). Furthermore, NO is a regulator of the opening of ATP-dependent potassium (K^+) channels and is thus responsible for the hyperpolarization of cell membranes (Rossi *et al.*, 2012). Also, it has been suggested that ATP sensitive K^+ channels of the mitochondria and elevated levels of NO might be involved in the mechanism of action of PBM (Karu, 2008; Karu *et al.*, 2005; Tuby *et al.*, 2006) in areas of the brain and heart (Karu, 2008; Karu *et al.*, 2004; Y.D. Ignatov, 2005). Thus given the dependency of both minoxidil and PBM on the aforementioned factors there is possibly some mechanistic overlap between the two modalities. A study conducted by Weiss *et al.* demonstrated that PBM was able to modulate 5- α reductase, the enzyme responsible for the conversion of testosterone to DHT, as well as alter the genetic expression of vascular endothelial growth factor (VEGF), which plays an influential role in hair follicle growth and thus PBM is able to stimulate hair growth (Castex-Rizzi *et al.*, 2002; Weiss *et al.*, 2005a,b; Yano and Detmar, 2001). Furthermore, it has been demonstrated that PBM may stimulate hair growth through modulation of inflammatory processes and immunological responses (Meneguzzo *et al.*, 2012). A study conducted by Wikramanayake *et al.* on C3H/HeJ AA mouse models supported this assumption, wherein the mice were exposed to a laser-comb and it was observed that the treatment led to an increase in the quantity of hair follicles where the majority of the follicles in anagen phase were seen to have decreased inflammatory infiltrates (Wikramanayake *et al.*, 2012a). Taking into account the disruptive effect that inflammatory infiltrates have on hair follicles along with the notion that several cytokines such as interferon gamma (IFN- γ), IL-1 α and β , TNF- α , MHC and Fas-antigen and macrophage migration inhibitory factor are all involved in cyclic hair growth as well as the pathogenesis of AA, PBM may be able to play significant role in the treatment of AA due to its modulating effects on inflammation (Wikramanayake *et al.*, 2012a).

A clinical study was carried out to investigate the effect of PBM on treatment of alopecia areata consisting of a sample size of 15 patients (6 men, 9 women) utilizing Super Lizer TM, a medical instrument operating on polarized linear light with a high output (1.8 W) of NIR radiation (600–1600 nm) possessing sufficient penetration depth to reach deep subcutaneous tissue (Yamazaki *et al.*, 2003). The patients received a 3 min laser treatment on the scalp either once a week or once every 2 weeks and were administered additional carpronium chloride 5% twice daily to all lesions (Yamazaki *et al.*, 2003). Supplemental oral antihistamines, cepharanthin and glycyrrhizin (extracts of medicinal Chinese herbs) were prescribed as well (Yamazaki *et al.*, 2003). The results of the study showed that 47% of the patients experienced hair growth 1.6 months earlier on areas irradiated with laser when compared to the areas that were not irradiated (Yamazaki *et al.*, 2003).

In another study 24 male androgenetic alopecia (AGA) patients were evaluated via global photography and phototrichogram using 655 nm red light and 780 nm IR light once a day for a period of 10 min (Kim *et al.*, 2007). Following 14 weeks of treatment significant increases in hair density and anagen/telogen ratio were observed at both the vertex and occiput, with 83% patients reporting that the treatment resulted in satisfactory results (Kim *et al.*, 2007).

Satino *et al.* conducted a study to investigate the efficacy of PBM on hair growth and tensile strength involving 28 male and 7 female AGA patients (Satino, 2003). Each patient was given a 655 nm HairMax LaserComb® to use at home for a period of 6 months, applying it for five to ten minutes per day on alternate days (Satino, 2003). Regarding the tensile strength of the hair, the results showed improvements in hair growth in all treated areas for both male and female sexes, however in the case of males the greatest improvements were observed in the vertex area whereas for females, the best improvements were seen in the temporal area (Satino, 2003). With regards to hair count, again all treated areas of both sexes showed improvement, but the vertex area showed the greatest improvement for the male patients (Satino, 2003). Leavitt *et al.* conducted a double-blind, sham device-controlled, multi-center, randomized 26 week trial where they tested the same device on 110 male AGA patients (Leavitt *et al.*, 2009). The patients were made to use the device three times a week for fifteen minutes for a total period of 26 weeks (Leavitt *et al.*, 2009). Noticeable increases in mean terminal density of hair were reported in the treatment group when compared to the sham treatment group (Leavitt *et al.*, 2009). Also, subjective assessment of the patients over the 26 week period reported prominent improvements in overall hair regrowth, decreased rate of hair loss, thicker feeling hair, scalp health and hair shine (Leavitt *et al.*, 2009).

Around 65% of the patients receiving chemotherapy for cancer develop alopecia which can have detrimental effects on psychological health of the patient (Trueb, 2009). It has been proposed that PBM could serve as treatment modality to stimulate and promote hair growth in cases of chemotherapy induced alopecia. In one study, a rat model was given varying regimens of chemotherapy in conjunction with PBM administered with a device possessing components (laser unit and switch, lacking comb or handle) of the Hair Max LaserComb (Wikramanayake *et al.*, 2012b). In all rats that were given laser treatment, hair regrowth occurred at a faster rate when compared to the sham treatment group. Additionally, PBM did not hinder the efficacy of the chemotherapeutic procedures (Wikramanayake *et al.*, 2012b).

PBM for fat reduction and cellulite treatment

In 2000 Neira *et al.* demonstrated the use of low level laser as a new alternative to liposuction, and successfully utilized it with doses that did not produce any detectable increases in tissue temperature or cause any noticeable macroscopic alterations in the tissue

structure (Neira *et al.*, 2000, 2002). Prior investigations concerned with the effects of LLLT on wound healing, pain relief and edema prevention paved the way for this therapeutic application (GD *et al.*, 1991; PR, 1989). The development of LLLT as a therapeutic modality to augment liposuction while avoiding macroscopic tissue alterations were based on determination of optimal parameters such as wavelength and power output for use (J.L., 2000). Evidence suggests that the best wavelengths suitable for biomodulation range between 630 and 640 nm (FAH. and XY., 1996; Frohlich, 1970, 1975; Fàà, 1968; Sroka *et al.*, 1997; van Breugel and Bar, 1992). Nierra *et al.* made several intriguing observations regarding the effects of LLLT on adipocytes. They utilized low level diode laser (635 nm) and a maximal power of 10 mW with energy values ranging from 1.2 to 3.6 J/cm² (Neira *et al.*, 2002). Using scanning electron microscopy (SEM) and transmission electron microscopy (TEM) it was demonstrated that adipocyte plasma membranes exhibited transitory pore formation as result of irradiation. It was formulated that this enabled the release of intracellular lipids from the adipocytes and thus supplemented the liposuction as it was expected to reduce the time taken for the procedure, allowed for extraction of greater volumes of fat and overall, reduced the energy expenditure of the surgeon.

Although the findings associated with LLLT enjoyed much praise and enthusiasm, an extensively study conducted put these findings surrounding LLLT into question (Brown *et al.*, 2004). In their study, cultured human preadipocytes did not show any differences when compared to non-irradiated cells after 60 min of irradiation using an LLLT source (635 nm and fluence 1 J/cm²) (Brown *et al.*, 2004). Furthermore, histological examination of lipoaspirates, in a porcine model exposed to LLLT for 30 min and human lipoaspirates, failed to demonstrate transitory pores when analyzed using SEM (Brown *et al.*, 2004). Additional data, raised questions regarding the ability of red light (635 nm) to effectively penetrate below the skin, into the sub-dermal tissues (Kolari and Airaksinen, 1993). Peter Foddor supportively stated: "One could postulate that the presence of the black dots on scanning electron microscopy images on the surface of fat cells reported by Neira *et al.* could represent an artifact." (Brown *et al.*, 2004). Since the data reported by Brown *et al.* from 2004, there have been several publications reporting the efficacy of LLLT.

In the original paper published by Neira *et al.* the fat liberating effects of LLLT on adipocytes were attributed to its ability to induce transitory micropores which were visualized with the help of SEM (Neira *et al.*, 2002). Furthermore, it was postulated that this stimulated the release of intracellular lipids from the adipocytes. Based on this, it was formulated that up to 99% of the fat stored within the adipocytes could be released and subsequently removed with the help of LLLT (635nm, 10 mW intensity, 6 min irradiation time) (Neira *et al.*, 2002). Re-cultured adipocytes exhibited a tendency to attain their native cellular conformation which was further confirmed by Caruso-Davis *et al.* utilizing a live-dead assay to assess the viability of these adipocytes following irradiation (Caruso-Davis *et al.*, 2011). Increase in ROS following LLLT has been proposed to bring about lipid peroxidation within the cell membrane which may cause damage and may present as the transitory pores. This may cause temporary damage that presents as transitory micropores. (Chen *et al.*, 2011; Geiger *et al.*, 1995; Karu, 2008; Tafur and Mills, 2008). However, when Brown *et al.* attempted to replicate Neira *et al.*'s findings (Neira *et al.*, 2002), they failed to visualize any transitory micropores via SEM (Brown *et al.*, 2004). No further SEM studies have documented these pores, but many publications have reported findings that indirectly support the transitory micropore formation theory. Another proposed mechanism that explains the release of intracellular lipids from adipocytes, suggests the activation of the complement cascade which is responsible for induction of adipocyte apoptosis and subsequent release of intracellular lipid components (Caruso-Davis *et al.*, 2011). To test the feasibility of this theory Caruso-Davis *et al.* exposed differentiated human adipocytes to plasma and exposed one group of cells to laser, while the control group received no laser intervention (Caruso-Davis *et al.*, 2011). No differences were noticed with regard to complement system components in either group and it was concluded that the LLLT did not act through activation of the complement cascade (Caruso-Davis *et al.*, 2011).

PBM for Vision and Hearing Problems

PBM has been used to treat disorders of sensory systems such as vision and hearing. Light can easily be shone into the eyes, and its known ability to heal and preserve cells and restore function means that PBM works well in the retina (Eells *et al.*, 2016; Geneva, 2016). It should be remembered that the retina is one of the most metabolically active tissue in the body, with a high demand for oxygen and glucose (Sanchez-Chavez *et al.*, 2012). Most studies of PBM for ophthalmology appear to have used red light (more specifically 670 nm from LEDs). PBM has been reported to be beneficial (in patients as well as in animal models) for age-related macular degeneration (Ivandic and Ivandic, 2008), diabetic retinopathy (Tang *et al.*, 2013, 2014), retinopathy of prematurity (Natoli *et al.*, 2013), light-induced photoreceptor degeneration (Albarracin *et al.*, 2011; Qu *et al.*, 2010), amblyopia (Ivandic and Ivandic, 2012), retinitis pigmentosa (Ivandic and Ivandic, 2014), and blindness caused by methanol toxicity (Eells *et al.*, 2003).

In a similar approach to shining light in the eyes for problems with vision, investigators have studied the effect of shining light in the ears to treat disorders of hearing. In this case however there is no ideal clear optical path for the light to get to the intended target cells in the inner ear. PBM has been studied for noise-induced hearing loss (Lee *et al.*, 2016; Tamura *et al.*, 2015), chronic tinnitus and sensorineural hearing loss (Tauber *et al.*, 2003), antibiotic-induced ototoxicity (Rhee *et al.*, 2013) and Meniere's disease (Teggi *et al.*, 2008).

PBM for Stroke

There are a plethora of plausible mechanisms (shown in Fig. 11) that suggest the beneficial effects of PBM on the brain will be pronounced, and this prediction has largely been proved to be true. Perhaps the most well-investigated application of PBM to the

Fig. 11 Many different mechanisms may contribute to the beneficial effects of PBMT on brain disorders.

brain, lies in its possible use as a treatment for acute stroke (Zhao *et al.*, 2015). Animal models such as rats and rabbits, were first used as laboratory models. These animals had experimental strokes induced by a variety of methods, and were then treated with light (usually 810 nm laser) within 24h of stroke onset (Peplow, 2015). In these studies intervention by tPBM within 24 h had meaningful beneficial effects. For the rat models, stroke was induced by middle cerebral artery occlusion (MCAO) via an insertion of a filament into the carotid artery or via craniotomy (Oron *et al.*, 2006). Stroke induction in the “rabbit small clot embolic model” (RSCM) was by injection of a preparation of small blood clots (made from blood taken from a second donor rabbit) into a catheter placed in the right internal carotid artery.

The promising results from pre-clinical animal studies led to a series of three clinical trials called being conducted for treatment of acute stroke in humans. These were called the “Neurothera Effectiveness and Safety Trials” (NEST-1 (Lampl *et al.*, 2007), NEST-2 (Huisa *et al.*, 2013), and NEST-3 (Zivin *et al.*, 2014)) using an 810 nm laser applied to the shaved head within 24 h of patients suffering an ischemic stroke. The first study, NEST-1, enrolled 120 patients between the ages of 40 to 85 years of age with a diagnosis of ischemic stroke involving a neurological deficit that could be measured. The purpose of this first clinical trial was to demonstrate the safety and effectiveness of laser therapy for stroke within 24h (Lampl *et al.*). tPBM significantly improved outcome in human stroke patients, when applied at ~18 h post-stroke, over the entire surface of the head (20 points in the 10/20 EEG system) regardless of stroke (Lampl *et al.*, 2007). Only one laser treatment was administered, and 5 days later, there was significantly greater improvement in the Real- but not in the Sham-treated group ($p < .05$, NIH Stroke Severity Scale). This significantly greater improvement was still present at 90 days post-stroke, where 70% of the patients treated with Real-PBM had a successful outcome, while only 51% of Sham-controls did. The second clinical trial, NEST-2, enrolled 660 patients, aged 40 to 90, who were randomly assigned to one of two groups (331 to PBM, 327 to sham) (Zivin *et al.*). Beneficial results ($p < .04$) were found for the moderate and moderate-severe (but not for the severe) stroke patients, who received the Real laser protocol (Zivin *et al.*, 2009). These results suggested that the overall severity of the individual stroke should be taken into consideration in future studies, and very severe patients are unlikely to recover with any kind of treatment. The last clinical trial, NEST-3, was planned for 1000 patients enrolled. Patients in this study were not to receive tissue plasminogen activator, but the study was prematurely terminated by the DSMB for futility (an expected lack of statistical significance) (Zivin *et al.*). NEST1 was considered successful, even though as a phase 1 trial, it was not designed to show efficacy. NEST2 was partially successful when the patients were stratified, to exclude

very severe strokes or strokes deep within the brain (Huisa *et al.*, 2013). There has been considerable discussion in the scientific literature on precisely why the NEST-3 trial failed (Lapchak and Boitano, 2016). Many commentators have wondered how could tPBM work so well in the first trial, in a sub-group in the second trial, and fail in the third trial. Lapchak's opinion is that the much thicker skull of humans compared to that of the other animals discussed above (mouse, rat and rabbit), meant that therapeutically effective amounts of light were unlikely to reach the brain (Lapchak and Boitano, 2016). Moreover the time between the occurrence of a stroke and initiation of the PBMT may be an important factor. There are reports in the literature that neuroprotection must be administered as soon as possible after a stroke (Lapchak, 2013a,b). Furthermore, stroke trials in particular should adhere to the RIGOR (rigorous research) guidelines and STAIR (stroke therapy academic industry roundtable) criteria (Lapchak *et al.*, 2013). Other contributory causes to the failure of NEST3 may have been included the decision to use only one single tPBM treatment, instead of a series of treatments. Moreover, the optimum brain areas to be treated in acute stroke remain to be determined. It is possible that certain areas of the brain that have sustained ischemic damage should be preferentially illuminated and not others.

Somewhat surprisingly, there have not as yet been many trials of PBM for rehabilitation of chronic stroke patients with only the occasional report to date. Naeser reported in an abstract the use of tPBM to treat chronic aphasia in post-stroke patients (Naeser *et al.*, 2012). Boonswang *et al.* (2012) reported a single patient case in which PBM was used in conjunction with physical therapy to rehabilitate chronic stroke damage. However the findings that PBM can stimulate synaptogenesis in mice with TBI, does suggest that tPBM may have particular benefits in rehabilitation of stroke patients. Norman Doidge, in Toronto, Canada has described the use of PBM as a component of a neuroplasticity approach to rehabilitate chronic stroke patients (Doidge, 2015).

PBM for Traumatic Brain Injury (TBI)

There have been a number of studies looking at the effects of PBM in animal models of TBI. Oron's group was the first (Oron *et al.*, 2007) to demonstrate that a single exposure of the mouse head to a NIR laser (808 nm) a few hours after creation of a TBI lesion could improve neurological performance and reduce the size of the brain lesion. A weight-drop device was used to induce a closed-head injury in the mice. An 808 nm diode laser with two energy densities (1.2–2.4 J/cm² over 2 min of irradiation with 10 and 20 mW/cm²) was delivered to the head 4 h after TBI was induced. Neurobehavioral function was assessed by the neurological severity score (NSS). There were no significant difference in NSS between the power densities (10 vs 20 mW/cm²) or significant differentiation between the control and laser treated group at early time points (24 and 48 h) post TBI. However, there was a significant improvement (27% lower NSS score) in the PBM group at times of 5 days to 4 weeks. The laser treated group also showed a smaller loss of cortical tissue than the sham group (Oron *et al.*).

Hamblin's laboratory then went on (in a series of papers (Oron *et al.*, 2007)) to show that 810nm laser (and 660nm laser) could benefit experimental TBI both in a closed head weight drop model (Wu *et al.*, 2012a), and also in controlled cortical impact model in mice (Ando *et al.*, 2011). Wu *et al.* (Wu *et al.*) explored the effect that varying the laser wavelengths of PBM had on closed-head TBI in mice. Mice were randomly assigned to PBM treated group or to sham group as a control. Closed-head injury (CHI) was induced via a weight drop apparatus. To analyze the severity of the TBI, the neurological severity score (NSS) was measured and recorded. The injured mice were then treated with varying wavelengths of laser (665, 730, 810 or 980 nm) at an energy level of 36 J/cm² at 4 h directed onto the scalp. The 665 nm and 810 nm groups showed significant improvement in NSS when compared to the control group at day 5 to day 28. Conversely, the 730 and 980 nm groups did not show a significant improvement in NSS and these wavelengths did not produce similar beneficial effects as in the 665 nm and 810 nm PBM groups (Wu *et al.*). The tissue chromophore cytochrome c oxidase (CCO) is proposed to be responsible for the underlying mechanism that produces the many PBM effects that are the byproduct of PBM. CCO has absorption bands around 665 nm and 810 nm while it has low absorption bands at the wavelength of 730 nm (Karu *et al.*). It should be noted that this particular study found that the 980 nm did not produce the same positive effects as the 665 nm and 810 nm wavelengths did; nevertheless previous studies did find that the 980 nm wavelength was an active one for PBM. Wu *et al.* proposed these dissimilar results may be due to the variance in the energy level, irradiance etc. between the other studies and this particular study (Wu *et al.*).

Ando *et al.* (2011) used the 810 nm wavelength laser parameters from the previous study and varied the pulse modes of the laser in a mouse model of TBI. These modes consisted of either pulsed wave at 10 Hz or at 100 (50% duty cycle) or continuous wave laser. For the mice, TBI was induced with a controlled cortical impact device via open craniotomy. A single treatment with an 810 nm Ga-Al-As diode laser with a power density of 50 mW/m² and an energy density of 36 J/cm² was given via tPBM to the closed head in mice for a duration of 12 min at 4 h post CCI. At 48 h to 28 days post TBI, all laser treated groups had significant decreases in the measured neurological severity score (NSS) when compared to the control. Although all laser treated groups had similar NSS improvement rates up to day 7, the PW 10 Hz group began to show greater improvement beyond this point. At day 28, the forced swim test for depression and anxiety was used and showed a significant decrease in the immobility time for the PW 10 Hz group. In the tail suspension test, which measures depression and anxiety, there was also a significant decrease in the immobility time at day 28, and this time also at day 1, in the PW 10 Hz group.

Studies using immunofluorescence of mouse brains showed that tPBM increased neuroprogenitor cells in the dentate gyrus (DG) and subventricular zone at 7 days after the treatment (Xuan *et al.*, 2013). The neurotrophin called brain derived neurotrophic factor (BDNF) was also increased in the DG and SVZ at 7 days, while the marker (synapsin-1) for synaptogenesis and neuroplasticity was increased in the cortex at 28 days but not in the DG, SVZ or at 7 days (Xuan *et al.*, 2015). Learning and memory as measured by the

Morris water maze was also improved by tPBM (Xuan *et al.*, 2014). Whalen's laboratory (Khuman *et al.*, 2012) and Whelan's laboratory (Quirk *et al.*, 2012) also successfully demonstrated therapeutic benefits of tPBM for TBI in mice and rats respectively.

Zhang *et al.* (2014) showed that secondary brain injury occurred to a worse degree in mice that had been genetically engineered to lack "Immediate Early Response" gene X-1 (IEX-1) when exposed to a gentle head impact (this injury is thought to closely resemble mild TBI in humans). Exposing IEX-1 knockout mice to PBM 4 h post injury, suppressed proinflammatory cytokine expression of interleukin (IL)-1 β and IL-6, but upregulated TNF- α . The lack of IEX-1 decreased ATP production, but exposing the injured brain to PBM elevated ATP production back to near normal levels.

Dong *et al.* (2015) even further improved the beneficial effects of PBM on TBI in mice, by combining the treatment with metabolic substrates such as pyruvate and/or lactate. The goal was to even further improve mitochondrial function. This combinatorial treatment was able to reverse memory and learning deficits in TBI mice back to normal levels, as well as leaving the hippocampal region completely protected from tissue loss; a stark contrast to that found in control TBI mice that exhibited severe tissue loss from secondary brain injury.

Margaret Naeser and collaborators have tested PBM in human subjects who had suffered TBI in the past (Naeser and Hamblin, 2015). Many sufferers from severe or even moderate TBI, have very long lasting and even life-changing sequelae (headaches, cognitive impairment, and difficulty sleeping) that prevent them working or living any kind of normal life. These individuals may have been high achievers before the accident that caused damage to their brain (McClure, 2011). Initially Naeser published a report (Naeser *et al.*, 2011) describing two cases she treated with PBM applied to the forehead twice a week. A 500 mW continuous wave LED source (mixture of 660 nm red and 830 nm NIR LEDs) with a power density of 22.2 mW/cm² (area of 22.48 cm²), was applied to the forehead for a typical duration of 10 min (13.3 J/cm²). In the first case study the patient reported that she could concentrate on tasks for a longer period of time (the time able to work at a computer increased from 30 min to 3 h). She had a better ability to remember what she read, decreased sensitivity when receiving haircuts in the spots where PBM was applied, and improved mathematical skills after undergoing PBM. The second patient had statistically significant improvements compared to prior neuropsychological tests after 9 months of treatment. The patient had a 2 standard deviation (SD) increase on tests of inhibition and inhibition accuracy (9th percentile to 63rd percentile) on the Stroop test for executive function and a 1 SD increase on the Wechsler Memory scale test for the logical memory test (83rd percentile to 99th percentile) (Naeser *et al.*, 2010).

Naeser *et al.* then went on to report a case series of a further eleven patients (Naeser *et al.*, 2010). This was an open protocol study that examined whether scalp application of red and near infrared (NIR) light could improve cognition in patients with chronic, mild traumatic brain injury (mTBI). This study had 11 participants ranging in age from 26 to 62 (6 males, 5 females) who suffered from persistent cognitive dysfunction after mTBI. The participants' injuries were caused by motor vehicle accidents, sports related events and for one participant, an improvised explosive device (IED) blast. tPBM consisted of 18 sessions (Monday, Wednesday, and Friday for 6 weeks) and commenced anywhere from 10 months to 8 years post-TBI. A total of 11 LED clusters (5.25 cm in diameter, 500 mW, 22.2 mW/cm², 13 J/cm²) were applied for about 10 min per session (5 or 6 LED placements per set, Set A and then Set B, in each session). Neuropsychological testing was performed pre-LED application and 1 week, 1 month and 2 months after the final treatment. Naeser and colleagues found that there was a significant positive linear trend observed for the Stroop Test for executive function, in trial 2 inhibition ($p=0.004$); Stroop, trial 4 inhibition switching ($p=0.003$); California Verbal Learning Test (CVLT)-II, total trials 1–5 ($p=0.003$); CVLT-II, long delay free recall ($p=0.006$). Improved sleep and fewer post-traumatic stress disorder (PTSD) symptoms, if present beforehand, were observed after treatment. Participants and family members also reported better social function and a better ability to perform interpersonal and occupational activities. Although these results were significant, further placebo-controlled studies will be needed to ensure the reliability of this these data (Naeser *et al.*, 2014).

Henderson and Morris (2015) used a high-power NIR laser (10–15 W at 810 and 980 nm) applied to the head to treat a patient with moderate TBI. The patient received 20 NIR applications over a 2 month period. They carried out anatomical magnetic resonance imaging (MRI) and perfusion single-photon emission computed tomography (SPECT). The patient showed decreased depression, anxiety, headache, and insomnia, whereas cognition and quality of life improved, accompanied by changes in the SPECT imaging.

PBM for Neurodegenerative Diseases

PBM has also been considered as a candidate for treating degenerative brain disorders such as Alzheimer's disease (AD), and Parkinson's disease (PD) (Moges *et al.*, 2009; Zhang *et al.*, 2008). Although only preliminary studies have so far been carried out, these are encouraging indications that merit further investigation.

Alzheimer's disease

There was a convincing study (De Taboada *et al.*, 2011) carried out in an A β PP transgenic mouse of AD. tPBM (810 nm laser) was administered at different doses 3 times/week for 6 months starting at 3 months of age. The numbers of A β plaques were significantly reduced in the brain with administration of tPBM in a dose-dependent fashion. tPBM mitigated the behavioral effects seen with advanced amyloid deposition and reduced the expression of inflammatory markers in the transgenic mice. In addition, TLT showed an increase in ATP levels, mitochondrial function, and c-fos expression suggesting there was an overall improvement in neurological function.

There has been a group of investigators in Northern England who have used a helmet containing 1072 nm LEDs to treat AD, but somewhat surprisingly no peer-reviewed publications have described this approach (see Relevant Website section). However a small pilot study (19 patients) that took the form of a randomized placebo-controlled trial investigated the effect of the Vielicht Neuro system (a combination of tPBM and intranasal PBM) on patients with dementia and mild cognitive impairment (Saltmarche *et al.*, 2016). This was a controlled single blind pilot study in humans to investigate the effects of PBM on memory and cognition. 19 participants with impaired memory/cognition were randomized into active and sham treatments over 12 weeks with a 4-week no-treatment follow-up period. They were assessed with MMSE and ADAS-cog scales. The protocol involved in-clinic use of a combined transcranial-intranasal PBM device; and at-home use of an intranasal-only PBM device and participants/caregivers noted daily experiences in a journal. Active participants with moderate to severe impairment (MMSE scores 5–24) showed significant improvements (5-points MMSE score) after 12 weeks. They also reported better sleep, fewer angry outbursts and decreased anxiety and wandering. Declines were noted during the 4 week no-treatment follow-up period. Participants with mild impairment to normal (MMSE scores of 25 to 30) in both the active and sham sub-groups showed improvements. No related adverse events were reported.

An interesting paper from Russia (Maksimovich, 2015) described the use of intravascular PBM to treat 89 patients with AD who received PBM (46 patients) or standard treatment with memantine and rivastigmine (43 patients). The PBM consisted of threading a fiber-optic through a catheter in the femoral artery and advancing it to the distal site of the anterior and middle cerebral arteries and delivering 20 mW of red laser for 20–40 min. The PBM group had improvement in cerebral microcirculation leading to permanent (from 1–7 years) reduction in dementia and cognitive recovery.

Parkinson's disease

The majority of studies on PBM for Parkinson's disease have been in animal models and have come from the laboratory of John Mitrofanis in Australia (Johnstone *et al.*, 2015). Two basic models of Parkinson's disease were used. The first employed administration of the small molecule (MPTP or 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) to mice (Shaw *et al.*, 2010). MPTP was discovered as an impurity in an illegal recreational drug to cause Parkinson's like symptoms (loss of substantia nigra cells) in young people who had taken this drug (Barcia, 2012). Mice were treated with tPBM (670-nm LED, 40 mW/cm², 3.6 J/cm²) 15 min after each MPTP injection repeated 4 times over 30 h. There were significantly more (35%–45%) dopaminergic cells in the brains of the tPBM treated mice (Shaw *et al.*, 2010). A subsequent study showed similar results in a chronic mouse model of MPTP-induced Parkinson's disease (Peoples *et al.*, 2012). They repeated their studies in another mouse model of Parkinson's disease, the tau transgenic mouse strain (K3) that has a progressive degeneration of dopaminergic cells in the substantia nigra pars compacta (SNc) (Purushothuman *et al.*, 2013). They went on to test a surgically implanted intracranial fiber designed to deliver either 670 nm LED (0.16 mW) or 670 nm laser (67 mW) into the lateral ventricle of the brain in MPTP-treated mice (Moro *et al.*, 2014). Both low power LED and high power laser were effective in preserving SNc cells, but the laser was considered to be unsuitable for long term use (6 days) due to excessive heat production. As mentioned above, these authors also reported a protective effect of abscopal light exposure (head shielded) in this mouse model (Johnstone *et al.*, 2014). Recently this group has tested their implanted fiber approach in a model of Parkinson's disease in adult Macaque monkeys treated with MPTP (El Massri *et al.*, 2016). Clinical evaluation of Parkinson's symptoms (posture, general activity, bradykinesia, and facial expression) in the monkeys were improved at low doses of light (24 J or 35 J) compared to high doses (125 J) (Moro *et al.*, 2016).

The only clinical report of PBM for Parkinson's disease in humans was an abstract presented in 2010 (Maloney *et al.*, 2010). Eight patients between 18 to 80 years with late stage PD participated in a non-controlled, non-randomized study. Participants received tPBM treatments of the head designed to deliver light to the brain stem, bilateral occipital, parietal, temporal and frontal lobes, and treatment along the sagittal suture. A Visual Analog Scale (VAS), was used to record the severity of their symptoms of balance, gait, freezing, cognitive function, rolling in bed, and difficulties with speech pre-procedure and at study endpoint with 10 being most severe and 0 as no symptom. Compared with baseline, all participants demonstrated a numerical improvement in the VAS from baseline to study endpoint. A statistically significant reduction in VAS rating for gait and cognitive function was observed with average mean change of -1.87 ($p < 0.05$) for gait and a mean reduction of -2.22 ($p < 0.05$) for cognitive function. Further, freezing and difficulty with speech ratings were significantly lower (mean reduction of 1.28 ($p < 0.05$) for freezing and 2.22 ($p < 0.05$) for difficulty with speech).

PBM for Psychiatric Disorders

A common and well-accepted animal model of depression is called "chronic mild stress" (Willner, 1997). After exposure to a series of chronic unpredictable mild stressors, animals develop symptoms seen in human depression, such as anhedonia (loss of the capacity to experience pleasure, a core symptom of major depressive disorder), weight loss or slower weight gain, decrease in locomotor activity, and sleep disorders (Anisman and Matheson, 2005). Wu *et al.* used Wistar rats to show that after 5 weeks of chronic stress, application of tPBM 3 times a week for 3 weeks (810 nm laser, 100 Hz with 20% duty cycle, 120 J/cm²) gave significant improvement in the forced swimming test (FST) (Wu *et al.*, 2012b). In a similar study Salehpour *et al.* (2016) compared the effects of two different lasers (630 nm at 89 mW/cm², and 810 nm at 562 mW/cm², both pulsed at 10 Hz, 50% duty cycle). The 810 nm laser proved better than the 630 nm laser in the FST, in the elevated plus maze and also reduced blood cortisol levels.

The first clinical study in depression and anxiety was published by Schiffer *et al.* in 2009 (Schiffer *et al.*, 2009). They used a fairly small area 1 W 810 nm LED array applied to the forehead in patients with major depression and anxiety. They found improvements in the Hamilton depression rating scale (HAM-D), and the Hamilton anxiety rating scale (HAM-A), 2 weeks after a single treatment. They also found increases in frontal pole regional cerebral blood flow (rCBF) during the light delivery using a commercial NIR spectroscopy device. Cassano and co-workers (Cassano *et al.*, 2015) used tPBM with an 810 nm laser (700 mW/cm² and a fluence of 84 J/cm² delivered per session for 6 sessions) in patients with major depression. Baseline mean HAM-D17 scores decreased from 19.8 ± 4.4 (SD) to 13 ± 5.35 (SD) after treatment ($P=0.004$).

Enhancement of Performance

PBM has been studied in two broad areas of performance enhancement, namely athletic performance and cognitive performance.

PBM for muscle and athletic performance

PBM has been used for prevention of muscle damage after exercise, including delayed onset muscle soreness, and improvement in muscle performance, demonstrated by increases in muscle torque, power or work; workload capacity; fatigue resistance; functional or sport activity, and exercise recovery.

The use of PBM to prevent muscle damage has been investigated in animal models, irradiating skeletal muscles before a bout of intense exercise (called in this chapter “muscular pre-conditioning”) and by following the muscle damage by measuring the creatine kinase (CK) levels in the bloodstream. The first study that used photobiomodulation by PBM to prevent muscle damage was carried out by Lopes-Martins *et al.* (2006) in rats. These authors investigated the effects of different doses of 655 nm laser (0.5 J/cm²; 1.0 J/cm² and 2.5 J/cm²) to prevent muscle fatigue and muscle damage (CK) induced by neuromuscular electrical stimulation. This study reported a PBM dose response to decrease CK activity.

Another experimental study used exercise-trained rats on an inclined treadmill and measured inhibition of inflammation, reduction of CK activity and reduction of oxidative stress. They also found increases in defense against oxidative stress (increased activity of superoxide dismutase) 24 h and 48 h after exercise (Gladwin and Shiva, 2009). These previous studies and other similar reports (de Almeida *et al.*, 2011; Leal *et al.*, 2010a,b; Liu *et al.*, 2009; Lopes-Martins *et al.*, 2006; Santos *et al.*, 2014; Sussai *et al.*, 2010) were important to establish the scientific basis to conduct clinical trials for the prevention of muscle damage by PBM.

Regarding clinical trials of improved muscle performance and exercise recovery, the first studies published were on delayed onset muscle soreness (Douris *et al.*, 2006; Vinck *et al.*, 2006) and resistance to muscle fatigue (Gorgey *et al.*, 2008; Leal *et al.*, 2008) during one or a few bouts of exercise; and improved muscle strength (Ferraresi *et al.*, 2011) and resistance to muscle fatigue (Vieira *et al.*, 2012) after exercise training programs combined with PBM. PBM has been tested in real life athletic competition such as in a team of volleyball players (Ferraresi *et al.*, 2015). A randomized double-blind placebo-controlled trial delivered PBM using LEDs (25 clusters of 4 infrared LEDs 850 nm, 130 mW and 25 clusters of 4 red LEDs 630 nm; 80 mW). PBM was applied over the *quadriceps femoris* muscles, hamstrings, and *triceps surae* of volleyball players before official matches. A professional male volleyball team (12 athletes) was randomized to receive one of four different total doses over each muscle group in a double-blind protocol. PBM at a dose of 210 J or higher avoided significant increases in creatine kinase (a marker of muscle damage) that were found in the placebo group.

PBM for enhancement of cognitive performance

The second area of performance enhancement by PBM (that is not yet as advanced as athletic performance) is the possibility of improving cognitive function in normal people or healthy animals using PBM. The first report was in middle aged (12 months) CD1 female mice (Michalikova *et al.*, 2008). Exposure of the mice to 1072 nm LED arrays led to improved performance in a 3D maze compared to sham treated age-matched controls. Francisco Gonzalez-Lima at the University of Texas Austin, has worked in this area for some time (Gonzalez-Lima and Barrett, 2014). Working in rats they showed that transcranial PBM (9 mW/cm² with 660 nm LED array) induced a dose-dependent increase in oxygen consumption of 5% after 1 J/cm² and 16% after 5 J/cm² (Rojas *et al.*, 2012). They also found that tPBM reduced fear renewal and prevented the reemergence of extinguished conditioned fear responses (Rojas *et al.*, 2012).

In normal human volunteers Gonzalez-Lima used transcranial PBM (1064 nm laser, 60 J/cm² at 250 mW/cm²) delivered to the forehead in a placebo-controlled, randomized study, to influence cognitive tasks related to the prefrontal cortex, including a psychomotor vigilance task (PVT), a delayed match-to-sample (DMS) memory task, and the positive and negative affect schedule (PANAS-X) to show improved mood (Barrett and Gonzalez-Lima, 2013). Subsequent studies in normal humans showed that tPBM with 1064 nm laser could improve performance in the Wisconsin Card Sorting Task (considered the gold standard test for executive function) (Blanco *et al.*, 2015). They also showed that tPBM to the right forehead (but not the left forehead) had better effects on improving attention bias modification (ABM) in humans with depression (Disner *et al.*, 2016).

A study by Salgado *et al.* used transcranial LED PBM on cerebral blood flow in healthy elderly women analyzed by transcranial Doppler ultrasound (TCD) of the right and left middle cerebral artery and basilar artery. Twenty-five non-institutionalized elderly women (mean age 72 years old), with cognitive status > 24, were assessed using TCD before and after transcranial LED therapy. tPBM (627 nm, 70 mW/cm², 10 J/cm²) was performed at four points of the frontal and parietal region for 30 s each twice a week for 4 weeks. There was a significant increase in the systolic and diastolic velocity of the left middle cerebral artery (25 and 30%,

respectively) and the basilar artery (up to 17 and 25%), as well as a decrease in the pulsatility index and resistance index values of the three cerebral arteries analyzed (Salgado *et al.*, 2015).

Conclusions

The goal of this chapter has been to argue the case that different aspects of photomedicine can exert two complementary, but completely opposite therapeutic effects. PDT can kill undesirable cells such as cancer cells and pathogenic microorganisms and remove unwanted tissue, while PBM can heal, restore and protect tissues that have been damaged or are at risk. Ironically both of these therapeutic approaches often use remarkably similar light parameters, namely wavelengths of red light (between 600 and 700 nm) at power densities and fluences that are also surprisingly comparable. However PBM is more versatile than PDT, which has an upper wavelength limit of about 800 nm. PBM on the other hand works very well with NIR light above 800 nm. In fact 810 nm is probably the single most popular wavelength for PBM. Several commentators have pointed out that the mechanisms of action of PDT and PBM have aspects in common; specifically the production of ROS (Lubart and Friedmann, 2011). However the amount of ROS produced is very different. In PDT the type of ROS (predominantly singlet oxygen and hydroxyl radicals produced in large quantities) produced by exogenously added PS are highly damaging to cells. These ROS are produced by photochemical reactions occurring between the administered PS and the light. By contrast the much lower amounts of ROS produced in PBM, arise from the action of light on the mitochondria inside the cells containing intrinsic chromophores, and are much less damaging, their duration is short, and they tend to stimulate protective responses and trigger signaling pathways.

We can illustrate the dual simultaneous use of PDT and PBM by describing an application of photomedicine in dentistry. Periodontitis is caused by pathogenic bacteria that accumulate in the dental pocket (between the tooth and the gums). An inflammatory response to these bacteria leads to production of matrix metalloproteinase enzymes that degrade the periodontal ligament eventually leading to tooth loss. PDT is used to treat periodontitis by injecting a small amount of a solution of methylene blue into the dental pocket and inserting a narrow fiber optic to deliver red light to excite the dye and kill the bacteria. However the red light spreads throughout the gingival tissue (containing no MB) where it acts to reduce inflammation and stimulate healing of the periodontal ligament. This dual action mechanism may explain why PDT is so effective for this condition.

Introduction

Light carries information about the sources from which it comes and the objects with which it interacts. Imaging can be defined as the physical or computational processing of this information in order to create a real or virtual replica (an “image”) of the source or object or its associated optical wavefield. This function can be performed by a physical imaging system, such as a classical lens-based system, as shown in Fig. 1. Alternatively, it can be implemented computationally, by a two-layer system composed of a physical interface, which senses the field produced by the object and a computational block that implements inversion algorithms to estimate the radiating object’s properties, which can, in turn, render image representations of that object and its surrounding field (see Fig. 2). The most critical property of an imaging system, be it physical or computational, is the degree of accuracy with which objects under surveillance can be successfully imaged or reproduced by that system. This characterization of the imaging system, usually termed “imaging resolution,” is affected by both fundamental physical limits (the inherent finite resolving power of the system, also termed the “diffraction limit”) as well as environmental effects (propagation model deviations) and sensor imperfections (aberrations). This contribution outlines the key principles to define and compute the resolution of typical imaging systems including those in which the phenomenon of multiple scattering can play a major role. Particular attention is given to the

Fig. 1 Physical imaging. In this lens-based system, imaging occurs if $1/d_1 + 1/d_2 = 1$ where F is the lens focal length.

Fig. 2 Computational Imaging.

intrinsic, fundamental resolution limit of the systems considered, which can be thought of as a fundamental bound to the resolution. The latter is indeed attainable in state-of-the-art systems (termed “diffraction-limited”).

Inverse Source and Scattering Problems

Two different forms of imaging are of interest in this contribution. The most basic one, to be termed here “source-field imaging,” involves the imaging of sources and their fields, and can be addressed within the theoretical framework of the inverse source problem (reconstruction of an unknown source from knowledge of its field in a region located outside the source support, such as in the far zone). This includes as a special case the inverse diffraction problem of reconstructing the field in a boundary or region from knowledge of the field in another region. The sources in question can be self-emitting (primary) or induced (secondary), as in a scatterer that is illuminated by light from another source (see Fig. 3). The second kind of imaging problem under consideration, to be termed “scatterer imaging,” involves the determination of a scatterer’s constitutive properties (e.g., spatial distribution of its index of refraction) from scattering data corresponding to a number of transmit-and-receive experiments.

In source-field imaging the associated mapping from the sought-after source or field (the object) to the field data is linear. In the classical theoretical formulations of this problem one can talk about a well-defined resolution limit arising from bandlimitation considerations in Fourier space. In contrast, in the scatterer imaging or inverse scattering problem, the associated forward map from scatterer properties to the data is, in general, nonlinear, so that alternative methods, such as the statistical Cramer–Rao bound (CRB) (Kay, 1993, chapter 3) need to be adopted so as to quantify the resolution (Sentenac *et al.*, 2007). Scattering has, however, a weak scatterer regime, called “the Born approximation,” in which the map in question is linear. This specialized regime is of interest in many practical applications and within it there is an associated classical resolution limit which has characteristics similar to those of the related source-field imaging problem.

Background and Literature

Resolution is traditionally quantified as the minimum distance that two point sources or scatterers can have while being distinguishable in the corresponding image. The image of a point source or scatterer is usually called the point spread function (PSF) of the imaging system. According to the well-known Rayleigh criterion (Goodman, 2005, p. 158), the resolution corresponds to the separation for which the peak of the image of one source occurs at the first null or zero of the image of the other. This is, however, only an approximate measure of resolution which applies, in fact, to a quite specific type of object. As pointed out by Toraldo di Francia in his classical studies on resolving power and information (Toraldo di Francia, 1952, 1955), imaging resolution is more appropriately characterized by the entire PSF and its associated information content, for example, in the spectral domain, from which one can in turn determine the effective dimensionality or number of degrees of freedom (NDF) of the entire imaging system. In many of the imaging problems that arise in optics, this detailed resolution characterization can be done quite conveniently in spatial Fourier domain, as we explain next for both inverse source and inverse scattering scenarios.

Among the major contributions to our understanding of imaging resolution and the associated field data “information content” and degrees of freedom of classical imaging systems, it is worthwhile mentioning the pioneering work of Abbe who established the resolution limit of the microscope around 1873 and Lord Rayleigh who further expanded the relevant theory in 1879 (Lord Rayleigh, 1879). Other contributions include those of Sparrow (1916), Schuster (1924), Houston (1927), and Buxton (1937), who proposed alternatives to the Rayleigh resolution criterion. Important advances at the crossroads of antenna theory, information theory, and optics were done in the 1940s and 1950s by several authors including Schelkunoff, Bouwkamp and Bruijn (1946), Woodward and Lawson (1948), and Toraldo di Francia (1955, 1952), which addressed the theoretical and practical

Fig. 3 Scattering experiment. The scatterer generates scattered field $\psi_s(\mathbf{r})$ in response to excitation or probing with incident field $\psi_i(\mathbf{r})$.

limits associated to the launching of and imaging with far fields. Among other results, these and other subsequent investigations (Ronchi, 1961; Rushforth and Harris, 1968) conclusively rendered the important insight that the resolution limits of far-field data are, for the most part, only practical (as opposed to theoretical), insofar as they are the result of noise and perturbations in realistic data and signal models. For example, if data were perfect and thus lacked noise, then it would be possible for many imaging systems (see Sections Propagating and Evanescent Spectra of the Radiated Field and Transverse Resolution of this article), to analytically extend the data corresponding to a region in Fourier space (called the visible region) into another one (called invisible) so as to increase the signal bandwidth and improve the resolution (Goodman, 2005; Section 6.6). This is one of the computational approaches to “superresolution” but it is useful only for perfect field data. In realistic systems, data are not perfect, and thus this approach is of limited practical applicability. But this illustrates that the conventional “fundamental” resolution limits are mostly practical, due to the almost inevitable presence of noise and perturbations, such as systematic errors. For instance, it is not impossible to physically process the far field, via a suitable device or instrument, so as to achieve superresolution. But (as in the computational case) such an analog or “physical processing” approach is viable only insofar as the physical field arriving at the instrument carries itself little noise or interference from spurious sources. Several promising approaches along these lines are mentioned in Section Superresolution, which are based on metamaterials. There we also mention other, more robust and already proven approaches to superresolution. Recent overviews on resolution and the related topic of superresolution can be found in den Dekker and van den Bos (1997), Heintzmann and Ficz (2006), Zheludev (2008), Testorf and Fiddy (2010).

Resolution in Source-Field Imaging

Scalar Wave Model

In the scalar approximation, the light emitted in free space by a monochromatic source oscillating at temporal frequency f (in Hertz) can be represented by a scalar wavefield whose spatial dependence is defined by a wavefunction $\psi(\mathbf{r})$ which obeys the inhomogeneous Helmholtz equation

$$(\nabla^2 + k_0^2)\psi(\mathbf{r}) = \rho(\mathbf{r}) \quad (1)$$

where $\mathbf{r} \in \mathbb{R}^3$, ρ represents the spatial dependence of the source (at said temporal frequency), ∇^2 is the Laplacian operator, and the wavenumber

$$k_0 = \omega/c = 2\pi/\lambda \quad (2)$$

where $\omega = 2\pi f$ is the angular oscillation frequency (in radians per second), c is the speed of light in free space, and λ is the wavelength. In this model of wave propagation, the wavefield $\psi(\mathbf{r})$ radiated by the source $\rho(\mathbf{r})$ is given by

$$\psi(\mathbf{r}) = \int_{\tau} d^3r' \rho(\mathbf{r}') G_0(\mathbf{r} - \mathbf{r}') \quad (3)$$

where d^3r' denotes differential volume, τ is the spatial support of the source, and G_0 is the free space Green function defined by

$$G_0(\mathbf{r} - \mathbf{r}') = -\frac{e^{ik_0|\mathbf{R}|}}{4\pi|\mathbf{R}|} \quad (4)$$

where $i = \sqrt{-1}$ and

$$\mathbf{R} = \mathbf{r} - \mathbf{r}' \quad (5)$$

Green's function G_0 admits a number of alternative representations, such as the Fourier-integral representation,

$$G_0(\mathbf{R}) = -\frac{1}{8\pi^3} \int_{-\infty}^{\infty} d^3K \frac{\exp(i\mathbf{K} \cdot \mathbf{R})}{k_0^2 - K^2 + i\varepsilon} \quad (6)$$

where $\mathbf{K} \in \mathbb{R}^3$, d^3K is differential volume in Fourier space, $K = |\mathbf{K}|$, and ε is an infinitesimal value added to remove the singularity at $K = k_0$.

Three-Dimensional Resolution of Far Fields

In many applications the fields are sensed in the far zone of the source region (τ), where $|\mathbf{r} - \mathbf{r}'| \simeq r - \hat{\mathbf{r}} \cdot \mathbf{r}'$, where $r = |\mathbf{r}|$ and $\hat{\mathbf{r}} = \mathbf{r}/r$, which when substituted in Eq. (4) gives the far zone behavior of G_0 ,

$$G_0(r\hat{\mathbf{r}} - \mathbf{r}') = -\frac{e^{ik_0r}}{4\pi r} e^{-ik_0\hat{\mathbf{r}} \cdot \mathbf{r}'} \quad (7)$$

Substituting this in Eq. (3) gives the far zone behavior of the field ψ ,

$$\psi(r\hat{\mathbf{r}}) \sim f(\hat{\mathbf{r}}) \frac{e^{ik_0r}}{r} \quad (8)$$

where the quantity $f(\hat{\mathbf{r}})$ is the far-field radiation pattern defined by

$$f(\hat{\mathbf{r}}) = -\frac{1}{4\pi} \int_{\tau} d^3 r \rho(\mathbf{r}) e^{-ik_0 \hat{\mathbf{r}} \cdot \mathbf{r}'} \quad (9)$$

The latter is, apart from a multiplicative factor, equal to the spatial Fourier transform of the source

$$\tilde{\rho}(\mathbf{K}) = \int_{\tau} d^3 r \rho(\mathbf{r}) e^{-i\mathbf{K} \cdot \mathbf{r}'} \quad (10)$$

evaluated at $\mathbf{K} = k_0 \hat{\mathbf{r}}$, i.e.,

$$f(\hat{\mathbf{r}}) = -\frac{1}{4\pi} \tilde{\rho}(\mathbf{K})|_{\mathbf{K} = k_0 \hat{\mathbf{r}}} \quad (11)$$

This means that the information about the source that is contained in the far field is the spatial Fourier transform of the source evaluated over the surface of a sphere, called the Ewald sphere (shown in Fig. 4), that has radius $K = k_0$ and is centered at the origin in Fourier space. The $K = k_0$ and $K \neq k_0$ components are sometimes referred to as the “on-the-shell” and “off-the-shell” components of the Fourier spectrum.

The fact that the far field carries only on-the-shell information about the spatial Fourier transform of ρ means that there is a loss of information about the source in the wave propagation process (from source to far field). This, in turn, implies that there is a fundamental limit to our capacity to reconstruct an unknown source from knowledge of the far field alone. It is, in fact, impossible to uniquely deduce the unknown source from the far field alone, since there are infinite nontrivial sources (called nonradiating sources) for which the spatial Fourier transform vanishes identically over the Ewald sphere (Devaney and Wolf, 1973; Bleistein and Cohen, 1977; Marengo and Ziolkowski, 2000; Gbur, 2003). One can, however, evaluate the unique, wavelike source which best fits the Fourier data over that sphere and has zero off-the-shell Fourier components. This is the classical approach to source imaging, and is the one that will lead us next to the fundamental resolution limit. Mathematically, this corresponds to the solution of minimum functional energy or 2 norm, or “minimum energy solution” (Devaney, 2012, chapter 5) to the inverse problem, without prior information about the source support. Minimum energy solutions consistent with a known source support can also be considered in certain applications (Marengo et al., 1999, 2000). In this case, the prior support information reliably enables superresolution (Schmidt-Weinmar, 1978).

The inverse problem of reconstructing an unknown source ρ , whose support τ is unknown, and that generates a given far-field radiation pattern $f(\hat{\mathbf{r}})$, with full-view data corresponding to 4π steradians, can thus be cast as computing the inverse Fourier transform (IFT) of the “on-the-shell” Fourier transform of the source. This is equivalent to Fourier inverting the quantity $\tilde{\rho}(\mathbf{K})H(\mathbf{K})$, where $H(\mathbf{K}) = \delta(K - k_0)/K^2$, which implies in view of the convolution theorem that the reconstructed source $\hat{\rho}$ is related to the source ρ by

$$\hat{\rho}(\mathbf{r}) = \int_{\tau} d^3 r' \rho(\mathbf{r}') h(\mathbf{r} - \mathbf{r}') \quad (12)$$

Fig. 4 Ewald sphere (left), and limiting Ewald sphere and ball (right) in 3D Fourier space. The Ewald sphere ($|\mathbf{K}| = k_0$) defines the Fourier domain region populated by far-field data of inverse source problems. The limiting Ewald ball ($|\mathbf{K}| \leq 2k_0$) defines the corresponding data region for full-view far-field inverse scattering within the weak scattering or first Born approximation. The figure also shows a shifted Ewald sphere ($|\mathbf{K} - k_0 \hat{\mathbf{y}}| = k_0$). It is contained inside the limiting Ewald ball, and corresponds to far-zone scattered field data under probing with a plane wave traveling in the direction of the unit vector $-\hat{\mathbf{y}}$. By probing the scatterer with plane waves traveling in all directions, the resulting scattered field data populates the entire limiting Ewald ball.

where the PSF h of this imaging system, equal to the IFT of H , can be shown to be given by

$$h(\mathbf{r} - \mathbf{r}') = \frac{1}{2\pi^2} j_0(k_0 |\mathbf{r} - \mathbf{r}'|) = -\frac{2}{\pi k_0} \text{Im} G_0(\mathbf{r} - \mathbf{r}') \quad (13)$$

where j_0 is the spherical Bessel function of the first kind and order 0 and Im denotes the imaginary part. A plot of this PSF is shown in Fig. 5. The first zero of $j_0(k_0 \Delta_{3D}^R)$ corresponding to $k_0 \Delta_{3D}^R = \pi$, gives a separation

$$\Delta_{3D}^R = \lambda/2 \quad (14)$$

which can be regarded, in view of the Rayleigh criterion, as the sought-after resolution that is attainable with this 3D, source-inversion-based computational imaging system. In particular, without the involvement of prior information about the source (such as support, parametric form, point-like nature, sparsity, or other), then two point sources are well resolved with far-field data only if they are separated by a distance equal to or greater than about half a wavelength.

Propagating and Evanescent Spectra of the Radiated Field

In many applications, field sensing is done over a plane, say $z = z_1$, which is itself contained in a half-space $z > z_0$ that is exterior to the source support τ , as shown in Fig. 6. In these applications, the field can be conveniently analyzed using a quite insightful classical representation called the angular-spectrum expansion, whose main features are outlined next.

Consider the Cartesian representation of $\mathbf{r}$ and $\mathbf{r}'$, in particular, $\mathbf{r} = (x, y, z)$ and $\mathbf{r}' = (x', y', z')$. Similarly, let $\mathbf{K} = (K_x, K_y, K_z)$. Let $\mathbf{R}_t = (x - x', y - y')$ and $\mathbf{K}_t = (K_x, K_y)$ denote the transverse components of $\mathbf{R}$ and $\mathbf{K}$, respectively, and introduce $Z = z - z'$. Then

$$\begin{aligned} \mathbf{R} &= \mathbf{R}_t + Z\hat{z} \\ \mathbf{K} &= \mathbf{K}_t + K_z\hat{z} \end{aligned} \quad (15)$$

Fig. 6 Geometry used in the discussion of the plane wave expansion of the radiated field.

Integrating over K_z in Eq. (6) one arrives, via classical contour integration in the complex plane (see Devaney, 2012, Section 4.1), to the Weyl expansion of Green's function G_0 , in particular,

$$G_0(\mathbf{R}) = -\frac{i}{8\pi^2} \int_{-\infty}^{\infty} d^2 K_t \frac{e^{i(\mathbf{K}_t \cdot \mathbf{R}_t \pm \gamma Z)}}{\gamma(\mathbf{K}_t)} \quad (16)$$

where “+” is used if $Z > 0$ and “−” if $Z < 0$ and

$$\gamma(\mathbf{K}_t) = \begin{cases} \sqrt{k_0^2 - K_t^2} & \text{if } K_t \leq k_0 \\ i\sqrt{K_t^2 - k_0^2} & \text{if } K_t > k_0 \end{cases} \quad (17)$$

where $K_t = |\mathbf{K}_t|$.

In view of Eq. (17), the integral in Eq. (16) can be conveniently decomposed into two parts, one corresponding to integration over the ball in two-dimensional $\mathbf{K}_t$ space defined by $K_t \leq k_0$, and another corresponding to integration over the complementary region (the exterior of this ball). These two regions are illustrated in Fig. 7. The waves associated to the $K_t \leq k_0$ region, sometimes called “the visible region,” are propagating, and go to the far zone, while the waves corresponding to the $K_t > k_0$ region, sometimes referred to as “the invisible region,” decay exponentially with $|Z|$ and are called evanescent. The latter carry the high-frequency features of G_0 but cannot be sensed effectively for $|Z|$ greater than a few wavelengths. Moreover, since this field representation can be applied to any $\hat{\mathbf{z}} \in S^2$ over the unit sphere S^2 , this further implies that these high-frequency, evanescent features of G_0 cannot be sensed a few wavelengths away from the source point $\mathbf{r}'$. For $|Z|$ greater than a few wavelengths, $G_0(\mathbf{R})$ can thus be approximated as

$$G_0(\mathbf{R}) \simeq -\frac{i}{8\pi^2} \int_{K_t \leq k_0} d^2 K_t \frac{e^{i(\mathbf{K}_t \cdot \mathbf{R}_t \pm \gamma Z)}}{\gamma(\mathbf{K}_t)} \quad (18)$$

This is a free field, obeying the homogeneous Helmholtz equation in all space.

Physically, the Weyl expansion (Eq. (16)) thus characterizes Green's function G_0 as superpositions (an spectrum) of two kinds of plane waves, namely, propagating and evanescent waves. The expansion coefficient $1/\gamma(\mathbf{K}_t)$ appearing in Eq. (16) can be thought of as the plane wave spectrum of G_0 . Its value in the visible and invisible regions defines the respective propagating and evanescent spectra of G_0 . Interestingly, it can be shown that (Devaney, 2012, p. 122)

$$\text{Im} G_0(\mathbf{R}) = -\frac{i}{8\pi^2} \int_{K_t \leq k_0} \frac{d^2 K_t}{\gamma(\mathbf{K}_t)} e^{i\mathbf{K}_t \cdot \mathbf{R}_t} \cos[\gamma(\mathbf{K}_t)Z] \quad (19)$$

hence the imaginary part of G_0 is determined only by the propagating spectrum. This is consistent with the fact, demonstrated earlier, that the imaginary part of G_0 governs, under conventional far-field sensing, the 3D imaging resolution, giving rise to the fundamental Rayleigh-criterion-based $\lambda/2$ resolution limit.

Now, using Eqs. (3) and (16) one finds that the field $\psi(\mathbf{r})$ can be represented for $z > z_0$ as

$$\psi(\mathbf{r}) = -\frac{i}{8\pi^2} \int_{-\infty}^{\infty} \frac{d^2 K_t}{\gamma(\mathbf{K}_t)} \hat{\rho}[\mathbf{K}_t + \gamma(\mathbf{K}_t)\hat{\mathbf{z}}] e^{i[\mathbf{K}_t \cdot \mathbf{r}_t + \gamma(\mathbf{K}_t)Z]} \quad (20)$$

where $\mathbf{r}_t = (x, y)$. Thus the corresponding plane wave spectrum of the field is governed by the spatial Fourier transform $\hat{\rho}$ of the source ρ , and its analytic continuation for complex argument, as required in connection with the evanescent portion of the field spectrum. For z near the boundary $z = z_0$ this field has significant evanescent components, which carry high-frequency information about the source and can thus lead to high imaging resolution in the associated inversion. On the other hand, $z - z_0$ greater than a

Fig. 7 Regions in Fourier domain corresponding to the visible (propagating) and invisible (evanescent) field components. The visible region is populated by far-field data.

few wavelengths the field is mostly propagating and can be approximated as

$$\psi(\mathbf{r}) = -\frac{i}{8\pi^2} \int_{K_t \leq k_0} \frac{d^2 K_t}{\gamma(\mathbf{K}_t)} \tilde{\rho}[\mathbf{K}_t + \gamma(\mathbf{K}_t)\hat{\mathbf{z}}] e^{i[\mathbf{K}_t \cdot \mathbf{r}_t + \gamma(\mathbf{K}_t)z]} \quad (21)$$

so that it carries only the low-frequency information about the source, which is in fact identical to the far-field one that lies in the Ewald sphere in the Fourier domain, as was explained earlier.

Transverse Resolution

In many optical imaging systems, such as in conventional microscopy, the object to be imaged lies over a planar surface. In this context it is convenient to characterize the resolution limits associated to the imaging of the field over a planar surface. Furthermore, this characterization is also relevant to the imaging of more arbitrary objects. In particular, it sheds insight on the resolution with which the near field in the vicinity of the object can be imaged, which is in turn linked to the resolution with which the object itself can be resolved. Thus, referring to the geometry in Fig. 6, we consider next the classical resolution associated to the imaging of the field over the boundary $z=z_0$ that bounds the support τ of radiating source ρ . It is assumed that the field data are gathered over the boundary $z=z_1$ where $z_1 - z_0$ is greater than several wavelengths so that the evanescent components cannot be reliably sensed there.

This can be addressed within the plane wave spectrum representation of the field by considering an equivalent Huygens' source linked to the field, for example, the double-layer singular surface source

$$\rho_s(\mathbf{r}) = -2\psi(\mathbf{r}_t, z_0)\delta'(z - z_0) \quad (22)$$

where $\delta'(z) = \frac{d}{dz}\delta(z)$, which leads to the first Rayleigh–Sommerfeld formula (Devaney, 2012, p. 75; Goodman, 2005, p. 48)

$$\psi(\mathbf{r}) = -2 \int_{-\infty}^{\infty} d^2 \mathbf{r}'_t \psi(\mathbf{r}'_t, z_0) \frac{\partial}{\partial z'} G_0(\mathbf{r} - \mathbf{r}'), \quad z > z_0 \quad (23)$$

Using this equivalent source in Eq. (21) one obtains

$$\psi(\mathbf{r}_t, z_1) = \frac{i}{4\pi^2} \int_{K_t \leq k_0} d^2 K_t \tilde{\psi}(\mathbf{K}_t, z_0) e^{i[\mathbf{K}_t \cdot \mathbf{r}_t + \gamma(\mathbf{K}_t)z_1]} \quad (24)$$

Therefore, the information about the near field at $z=z_0$ that is contained in the measured field at $z=z_1$ is its 2D spatial Fourier transform $\tilde{\psi}(\mathbf{K}_t, z_0)$ evaluated over the ball of radius k_0 centered at the origin in 2D Fourier space (the visible region shown in Fig. 7). This means that the largest spatial frequency magnitude contained in the data is $k_0 = 2\pi/\lambda$, so that the minimum spatial period that can be resolved is λ . This is a fundamental measure of the achievable resolution, in particular,

$$\Delta_{2D} = \lambda \quad (25)$$

based on standard bandlimitation considerations. In addition, one can also consider the Rayleigh resolution criterion. For this purpose, we note that the transfer function of the propagation map is $H(\mathbf{K}_t) = U(k_0 - K_t)$ where U is the unit-step function. The respective IFT corresponds to the PSF h of the imaging system which can be shown to be equal to

$$h(\mathbf{r}_t) = 2\pi k_0 J_1(k_0 \rho) / \rho \quad (26)$$

where $\rho = |\mathbf{r}_t|$. A plot of this PSF is shown in Fig. 5. The first zero of this PSF occurs at $k_0 \rho \approx 1.22\pi$, corresponding to a (Rayleigh-criterion-based) 2D or transverse field resolution of

$$\Delta_{2D}^R = 0.61\lambda \quad (27)$$

This corresponds to the resolution limit if the field is sensed over the entire plane $z=z_1$. In addition to the intrinsic loss of information (the evanescent wave part) due to wave propagation, there is also an additional loss due to the finite size of the sensing apparatus. In this realistic case if the aperture covers a polar angle 2θ then the detected transverse frequencies are such that $K_t \leq k_0 \sin \theta$ and therefore the respective PSF is

$$h(\mathbf{r}_t) = 2\pi k_0 \sin \theta J_1(k_0 \sin \theta \rho) / \rho \quad (28)$$

which gives the Rayleigh criterion transverse resolution

$$\Delta_{2D}^R = \frac{0.61\lambda}{\text{NA}} \quad (29)$$

where $\text{NA} = \sin \theta$ is the numerical aperture of the apparatus.

Resolution in Scatterer Imaging

In many application areas (such as radar, lidar, biomedical imaging, geophysical imaging, nondestructive testing, to mention a few) a medium is probed using known incident waves, and the medium's response, in the form of the resulting perturbation or scattered waves, is measured with sensors located in the far zone (see Fig. 3). By processing the measured scattered field data, it is possible to obtain images of the scattering medium or target, which give information about its localization, shape, and material

properties (e.g., index of refraction). If the surrounding background medium is free space, then the scattered field, to be denoted as $\psi_s(\mathbf{r})$, obeys, within the scalar formulation, a differential equation of the form

$$(\nabla^2 + k_0^2)\psi_s(\mathbf{r}) = V(\mathbf{r})\psi(\mathbf{r}) \quad (30)$$

where k_0 is the wavenumber in free space, $V(\mathbf{r})$ is the space-dependent scattering potential, which is related to the scatterer's space-dependent index of refraction $n(\mathbf{r})$ via

$$V(\mathbf{r}) = k_0^2[1 - n^2(\mathbf{r})] \quad (31)$$

and $\psi(\mathbf{r})$ is the total field, which is given by

$$\psi(\mathbf{r}) = \psi_i(\mathbf{r}) + \psi_s(\mathbf{r}) \quad (32)$$

where $\psi_i(\mathbf{r})$ is the probing or incident field and the scattered field $\psi_s(\mathbf{r})$ obeys the radiation condition at infinity, as required by causality considerations.

It follows from Eqs. (1), (3), and (30) (via the substitution $\rho \rightarrow V\psi$) that

$$\psi_s(\mathbf{r}) = \int_{\tau} d^3r' G_0(\mathbf{r} - \mathbf{r}') V(\mathbf{r}') \psi(\mathbf{r}') \quad (33)$$

where τ denotes the scatterer's support. Furthermore, using Eq. (7) in Eq. (33) we obtain (in analogy to Eqs. (8) and (9)) the far zone behavior of the scattered field:

$$\psi(r\mathbf{s}) \sim f_s(\mathbf{s}; \psi_i) \frac{e^{ik_0 r}}{r} \quad (34)$$

where the quantity $f_s(\mathbf{s}; \psi_i)$ is the far-zone scattering amplitude, which depends on the observation direction $\mathbf{s} \in S^2$ and the incident field ψ_i , and is given by

$$f(\hat{\mathbf{r}}) = -\frac{1}{4\pi} \int_{\tau} d^3r V(\mathbf{r}) \psi(\mathbf{r}) e^{-ik_0 \mathbf{s} \cdot \mathbf{r}} \quad (35)$$

For the typical situation in which the incident field is a uniform plane wave traveling in the direction of the unit vector $\mathbf{s}_0$, i.e.,

$$\psi_i(\mathbf{r}) = e^{ik_0 \mathbf{s}_0 \cdot \mathbf{r}} \quad (36)$$

then it is convenient to denote $f_s(\mathbf{s}; \psi_i)$ as $f_s(\mathbf{s}; \mathbf{s}_0)$. For this case we obtain from Eqs. (32), (35), and (36)

$$f_s(\mathbf{s}; \mathbf{s}_0) = f_s^B(\mathbf{s}; \mathbf{s}_0) + f_s^{MS}(\mathbf{s}; \mathbf{s}_0) \quad (37)$$

where f_s^B is the scattering amplitude under the weak scattering or Born approximation, which is given by

$$f_s^B(\mathbf{s}; \mathbf{s}_0) = -\frac{1}{4\pi} \int_{\tau} d^3r V(\mathbf{r}) e^{-ik_0(\mathbf{s} - \mathbf{s}_0) \cdot \mathbf{r}} = -\frac{1}{4\pi} \tilde{V}(\mathbf{K})|_{\mathbf{K} = k_0(\mathbf{s} - \mathbf{s}_0)} \quad (38)$$

where $\tilde{V}$ denotes the spatial Fourier transform of the scattering potential function V , and f_s^{MS} is the multiple scattering contribution to the total scattering amplitude, which is given by

$$f_s^{MS}(\mathbf{s}; \mathbf{s}_0) = -\frac{1}{4\pi} \int_{\tau} d^3r V(\mathbf{r}) \psi_s(\mathbf{r}) e^{-ik_0 \mathbf{s} \cdot \mathbf{r}} \quad (39)$$

If multiple scattering is weak, so that $|\psi_s| \ll |\psi_i|$ and consequently $|f_s^{MS}| \ll |f_s^B|$ then from Eq. (37) approximately

$$f_s(\mathbf{s}; \mathbf{s}_0) \simeq f_s^B(\mathbf{s}; \mathbf{s}_0) \quad (40)$$

and according to Eq. (38) the scattering amplitude is given by the spatial Fourier transform $\tilde{V}$ of the scattering potential V evaluated at $\mathbf{K} = k_0(\mathbf{s} - \mathbf{s}_0)$. If the scattering amplitude is measured for a fixed incidence direction $\mathbf{s}_0$ and for all the observation directions $\mathbf{s}$, the resulting scattering data populates the shifted Ewald sphere where $|\mathbf{K} - k_0 \mathbf{s}_0| = k_0$ (see Fig. 4). If probing is done using all the incidence directions $\mathbf{s}_0$ and sensing is done in all observation directions $\mathbf{s}$ then the resulting scattering data populates in Fourier space a ball of radius $2k_0$ that is centered at the origin. It is bounded by the so-called limiting Ewald sphere, and is illustrated and referred to as the limiting Ewald ball in Fig. 4. We focus next on this situation of full-view probing and sensing. In this weak scattering regime, the map from the scattering potential V to the scattering amplitude is linear, so that one can compute a well-defined PSF for the relevant computational imaging. The PSF in question is given by (Simonetti, 2006, Eq. (17))

$$h(\mathbf{r}) = \frac{8j_1(2k_0 r)}{\lambda^2 r} \quad (41)$$

A plot of this PSF is shown in Fig. 5. Based on the first zero of the spherical Bessel function j_1 (whose approximate value is 4.493), an approximate value of the Born approximation scattering resolution based on Rayleigh's criterion is

$$\Delta_{3D}^R \simeq 0.358\lambda \quad (42)$$

But this is only a rough resolution estimate. Moreover, it is pertinent only for the special case of two point-like scatterers. It is more general to simply state that the largest spatial frequency magnitude contained in the data is $2k_0 = 4\pi/\lambda$ which implies, in turn, that the minimum spatial period that can be resolved is $\lambda/2$, and this is the familiar resolution limit discussed in Wolf's classical treatment of the inverse scattering problem in the framework of the Born approximation (Wolf, 1969, Eq. (22)). In particular,

based on this minimum spatial period criterion which is relevant to arbitrary scatterers,

$$\Delta_{3D,s} = \lambda/2 \quad (43)$$

On the other hand, if multiple scattering is not negligible, then the scattering amplitude is given by Eq. (37) where the term f_s^{MS} is given by Eq. (39) and cannot be neglected. Substituting from Eq. (33) in Eq. (39) we find that

$$\begin{aligned} f_s^{\text{MS}}(\mathbf{s}; \mathbf{s}_0) &= -\frac{1}{4\pi} \int_{\tau} d^3r V(\mathbf{r}) \psi_s(\mathbf{r}) e^{-ik_0 \mathbf{s} \cdot \mathbf{r}} \\ &= -\frac{1}{4\pi} \int_{\tau} d^3r V(\mathbf{r}) e^{-ik_0 \mathbf{s} \cdot \mathbf{r}} \int_{\tau} d^3r' G_0(\mathbf{r} - \mathbf{r}') V(\mathbf{r}') \psi(\mathbf{r}') \end{aligned} \quad (44)$$

which clearly showcases the nonlinear nature of the map from V to f_s^{MS} (and, in turn, to f_s). This prohibits the use of bandlimitation considerations in Fourier domain to quantify the corresponding imaging resolution. Alternative criteria that apply also to nonlinear systems, such as a criterion based on the fundamental CRB have been proposed (Sentenac *et al.*, 2007), and applied to quantify the effects of multiple scattering in imaging (Sentenac *et al.*, 2007; Simonetti *et al.*, 2008; Marengo and Berestesky, 2013; Marengo *et al.*, 2012).

Simonetti (2006) has shown that multiple scattering can enhance imaging resolution, relative to the Born-approximation-based resolution limits, thanks to the conversion of evanescent waves in the scatterer into propagating waves that are accessible in the far zone. This mechanism implies the encoding of high-frequency information about the scatterer, beyond that associated (in the weak scattering approximation) to the limiting Ewald ball. Thus superresolution is possible thanks to multiple scattering. The key argument can be outlined with the help of Eqs. (6) and (44). Using Eq. (6) in Eq. (44) one obtains

$$f_s^{\text{MS}}(\mathbf{s}; \mathbf{s}_0) = -\frac{1}{4\pi} \int d^3K \frac{\tilde{V}(k_0 \mathbf{s}_0 - \mathbf{K}) T(\mathbf{K}, k_0 \mathbf{s}_0)}{k_0^2 - K^2 + i\epsilon} \quad (45)$$

where

$$T(\mathbf{K}, k_0 \mathbf{s}_0) = \int_{\tau} d^3r \rho(\mathbf{r}) e^{-i\mathbf{K} \cdot \mathbf{r}} V(\mathbf{r}) \psi(\mathbf{r}) \quad (46)$$

The integral in Eq. (45) is over the entire $\mathbf{K}$ space, so that it depends on the value of the spatial Fourier transform $\tilde{V}$ of V for all spatial frequencies, including those outside the limiting Ewald ball. As a result, it is possible, thanks to multiple scattering, to encode information in the far-field scattering amplitude about the high spatial frequencies of the object corresponding to the exterior of the limiting Ewald ball, leading to the possibility of superresolution.

There is a lot of evidence that multiple scattering can, indeed, lead to superresolution. This includes evidence based on experimental data (Chen and Chew, 1998), numerical inversions incorporating multiple scattering (Cui *et al.*, 2004; Belkebir *et al.*, 2006), and algorithm-independent, estimation-theoretic studies based on the fundamental CRB corresponding to a given noise level (Sentenac *et al.*, 2007; Simonetti *et al.*, 2008; Marengo and Berestesky, 2013). On the other hand, it has been found that while multiple scattering is typically beneficial and enables superresolution beyond what is possible for weak scatterers obeying the Born approximation, for certain sensing conditions its impact is minor and can even be detrimental (Sentenac *et al.*, 2007; Marengo and Berestesky, 2013). The quantification of the role of multiple scattering in superresolution is so far inconclusive and is an important area of ongoing research.

Superresolution

The resolution limit discussed so far applies to conventional imaging systems employing far-field probing (involving propagating waves only) and far-field sensing. If the interrogation of the object involves probing or sensing in the near zone, then imaging resolution is greatly improved (leading to “superresolution”) thanks to the sensing of the high-frequency information about the object that is contained in the corresponding near-field evanescent waves. This is the idea behind near-field optics techniques such as near-field scanning microscopy (Betzig and Trautman, 1992) and total internal reflection tomography (Carney and Schotland, 2001; Chaumet *et al.*, 2004).

Another approach to superresolution is based on the analyticity of the radiated fields, and consists of analytically continuing the field data associated to the propagating (or visible) region of the plane wave spectrum into the complementary evanescent (or invisible) region of the spectrum (Goodman, 2005, Section 6.6). However, the required analytic continuation is highly sensitive to noise in the data, and consequently this method is hard to implement in practice. A more reliable methodology which is well-known (Schmidt-Weinmar, 1978) to render superresolution in many applications is to incorporate into the inversion and imaging algorithms prior information about the object, such as support information (see Marengo *et al.*, 1999, 2000; Schmidt-Weinmar, 1978; Marengo, 2014; Goodman, 2005, Section 6.6.4). In the latter approach, the superresolution is due to the exploitation of prior information about the sought-after object. Here it is important to emphasize that the focus of the present contribution has been on the classical assessment of resolution, in which no prior information about the object is assumed. In modern imaging, several techniques have emerged which successfully exploit prior information, and can even achieve superresolution thanks to the relevant prior. In this connection, the incorporation of sparsity priors by means of the methods of compressive sensing has been particularly successful (Candes, 2006).

Recently, there has also been a lot of interest in achieving superresolution via direct physical imaging using innovative devices and sensors. One of these approaches is the so-called superlens proposed by Pendry (2000), in which left-handed metamaterials play a key role. In these approaches, the idea is to build a device that can amplify or sense in the far zone the evanescent waves emanating from a radiating object. The experimental realization has been pursued by many groups (Grbic and Eleftheriades, 2004), and several alternative technologies such as the hyperlens (Jacob *et al.*, 2006) have also been proposed.

Coherent Diffractive Imaging

Introduction

The infamous “phase problem” stems from that optical detection devices (e.g., charge-coupled devices, photodetectors, and human eyes) cannot directly record the phase of the electromagnetic field (at 10^{15} Hz and higher), but only the average power, which is proportional to the magnitude square of the field. As a result, obtaining phase involves additional complexity, both experimentally and computationally.

In general, the first step of solving the phase problem is to convert the originally “invisible” phase information to the observable intensity variations, i.e., phase contrast. In fact, any *complex* transfer function will produce some phase contrast. For example, the Zernike phase contrast is achieved by introducing a $\pi/2$ phase shift (and thus a pure imaginary transfer function component) to the direct illumination beam. The second step is to carry out a phase retrieval procedure to computationally recover the quantitative phase values.

Many techniques have been developed to recover phase information. Depending on the physical mechanism of realizing phase contrast, they can be broadly categorized into interferometric and “non-interferometric” techniques – the former relies on interferometry and the latter does not. Here, we focus on the non-interferometric techniques. A distinctive advantage of these techniques is that phase contrast can be produced simply by some diffraction process, which means that the experimental setup can be made simple (e.g., lensless). The non-interferometric techniques are often referred to as “coherent diffractive imaging (CDI),” emphasizing the role of diffraction in forming phase contrast. As compared to interferometry, CDI often requires more sophisticated computational algorithms to reconstruct the phase, since the diffraction measurements are often related to the phase by nonlinear equations.

From a theoretical point of view, phase retrieval may not have a unique solution; furthermore, even if a unique solution exists, it is not guaranteed that the algorithm will converge to the global solution because the underlying problem is nonlinear and nonconvex. The success of the phase retrieval algorithms depends on not only the numerical procedure itself, but also the physical measurement process that defines the nonlinear problem to solve. Generally speaking, successful phase retrieval requires both redundancy and diversity in the data. The optimal design involves trade-offs between experimental complexity, cost, accuracy, and computational requirement. The optimal implementation is highly application dependent, which requires joint designs of physical optical instrumentation and computation.

Fourier Measurement-Based Techniques

The Fourier measurement is the most widely used method in CDI. A typical experimental setup based on far-field diffraction is illustrated in Fig. 1. Under coherent illumination, the measured far-field intensity is simply the Fourier intensity of the object,

$$I(\mathbf{u}) = \left| \int g(\mathbf{r}) \exp\{-i2\pi\mathbf{r} \cdot \mathbf{u}\} d^2\mathbf{r} \right|^2 = |\mathcal{F}\{g\}|^2 \quad (1)$$

where $\mathcal{F}\{\cdot\}$ denotes the two-dimensional (2D) Fourier transform (FT), $g(\mathbf{r}) = |g(\mathbf{r})| \exp\{i\phi(\mathbf{r})\}$ is the object’s complex transmittance function having amplitude $|g(\mathbf{r})|$ and phase $\phi(\mathbf{r})$, and $\mathbf{r}$ and $\mathbf{u}$ denote the spatial and Fourier coordinates, respectively. The knowledge of the Fourier intensity alone does not allow unique recovery of the object, since there are infinitely many possible phase functions that satisfy the equation. The general strategy is to introduce additional prior knowledge and/or constraints to

Fig. 1 Schematics of the Fourier measurement-based coherent diffractive imaging (CDI) technique.

regularize the problem. In the following, we will describe different algorithms that have been designed for solving problems that incorporate different priors.

Alternating Projection Algorithms

Alternating projection is the most popular class of phase retrieval algorithms. The general idea is to treat the constraint at the Fourier domain as one set, and the constraint at the real-space (at the object plane) as the other. The algorithm then iteratively updates the solution by projecting the estimated field between the two sets in an alternating order.

The pioneering work of Gerchberg and Saxton (GS) in 1972 assumes both the Fourier magnitude $|G(\mathbf{u})| = \sqrt{I(\mathbf{u})}$ and the real-space magnitude $|g(\mathbf{r})|$ are known. The algorithm starts with some phase initial guess at the real space, for example, all-zero phase or uniformly random-distributed values within certain range. It then iteratively imposes the real-space and Fourier magnitude constraints in the following four steps, as illustrated in Fig. 2. In the s th iteration, the algorithm first takes the FT of the estimated object $g_s(\mathbf{r})$ to get the estimated Fourier spectrum $G_s(\mathbf{u})$,

$$G_s(\mathbf{r}) = \mathcal{F}\{g_s(\mathbf{u})\} \quad (2)$$

Second, the computed Fourier magnitude is then replaced by the measurement, while keeping the estimated phase unchanged.

$$G'_s(\mathbf{u}) = G_s(\mathbf{u}) \cdot \frac{\sqrt{I(\mathbf{u})}}{|G_s(\mathbf{u})|} \quad (3)$$

Third, it takes the inverse FT, $\mathcal{F}^{-1}\{\cdot\}$, of the updated Fourier spectrum $G'_s(\mathbf{u})$ to update the object field $g'_s(\mathbf{r})$,

$$g'_s(\mathbf{r}) = \mathcal{F}^{-1}\{G'_s(\mathbf{u})\} \quad (4)$$

Fourth, the real-space magnitude constraint is imposed by replacing the estimate with the known values, while keeping the estimated phase unchanged.

$$g_{s+1}^{\text{GS}}(\mathbf{r}) = |g(\mathbf{r})| \cdot \frac{g'_s(\mathbf{r})}{|g'_s(\mathbf{r})|} \quad (5)$$

The iteration continues until the reconstruction error between the estimated and the measured Fourier magnitude, $\sum_{\mathbf{u}} ||G_s(\mathbf{u})| - \sqrt{I(\mathbf{u})}|$, below certain value.

The error-reduction (ER) algorithm proposed by Fienup in 1978 extends the GS algorithm to incorporate other types of priors, such as the object support and nonnegativity constraints. The ER algorithm follows the similar four steps in each iteration.

The only difference is in the fourth step, in which other real-space constraints are imposed by

$$g_{s+1}^{\text{ER}}(\mathbf{r}) = \begin{cases} g'_s(\mathbf{r}), & m \notin \gamma \\ 0, & m \in \gamma \end{cases} \quad (6)$$

where γ defines the set of indices for which $g'_s(\mathbf{r})$ violates the real-space constraints.

Fig. 2 Block diagram of the Gerchberg–Saxton (GS), error reduction (ER), hybrid input–output (HIO), and oversampling smoothness (OSS) algorithms.

The reconstruction errors of both GS and ER algorithms are shown to be monotonically decreasing with iterations. Despite this convergence property, it is not guaranteed that the true solution can be found, since the algorithm may converge to a local minimum. The underlying problem, which can be written in the form of a multivariate minimization of a cost function with respect to the unknown phase function, is both nonlinear and nonconvex in a high-dimensional space. Here, the (non)convexity characterizes the hyper-surface formed by the cost function. A nonconvex surface consists of multiple peaks and valleys, which implies the existence of multiple local minimal solutions.

The hybrid input–output (HIO) algorithm is another commonly used alternating projection algorithm. It follows the same iterative framework as GS and ER with a modification to the fourth step, as given by

$$g_{s+1}^{\text{HIO}}(\mathbf{r}) = \begin{cases} g_s'(\mathbf{r}), & m \notin \gamma \\ g_s(\mathbf{r}) - \beta g_s'(\mathbf{r}), & m \in \gamma \end{cases} \quad (7)$$

where β is a feedback constant, with a typical value between 0.5 and 1. Empirically, it is shown that HIO is able to avoid local minima and converges to the global solution in the noise-free case. In practice, the solution tends to oscillate as the iteration increases. The algorithm may stagnate and fails to converge to the global minimum.

Many algorithms have been developed to overcome these limitations, including the combination of HIO and ER, solvent flipping (SF), different map (DM), hybrid projection–reflection (HPR), average successive reflections (ASR), relaxed averaged alternating reflectors (RAAR), oversampling smoothness (OSS), and continuous HIO (CHOI). As an example, both CHIO and OSS attempt to smooth the updates by removing sharp transitions in the estimates. The OSS update is related to HIO by

$$g_{s+1}^{\text{OSS}}(\mathbf{r}) = \begin{cases} g_{s+1}^{\text{HIO}}(\mathbf{r}), & m \notin \gamma \\ g_{s+1}^{\text{HIO}}(\mathbf{r}) * w_s(\mathbf{r}), & m \in \gamma \end{cases} \quad (8)$$

where $*$ denotes convolution. For the set of indices that violates the real-space constraints, the HIO solution is low-pass filtered by a Gaussian function $w_s(\mathbf{r})$, whose variance increases with iterations.

The convergence property of HIO and its variants is greatly affected by the support constraint. In many applications, the support is not exactly known a priori. Estimation techniques have been developed based on the support of the object's auto-correlation function (i.e., FT of the measured Fourier intensity). The support can be further refined during iterations using the “shrink-wrap” algorithm.

The performance of the alternating projection phase retrieval algorithm is also dependent on the initial guess and it may converge to different solutions due to the nonconvexity of the problem. Initializations with different random phase distributions have been proposed. The final solution is then constructed by some numerical averaging scheme. For example, the phase retrieval transform function (PRTF) is proposed to quantify the computationally recovered spatial resolution, as defined by

$$\text{PRTF}(\mathbf{u}) = \langle |\mathcal{F}\{\hat{g}_t(\mathbf{r})\}| \rangle_t / \sqrt{I(\mathbf{u})} \quad (9)$$

where $\hat{g}_t(\mathbf{r})$ denotes the estimated object from the t th reconstruction, and $\langle \cdot \rangle$ takes the average over all the reconstructions using different initial guesses. In cases where a low-resolution object is known or can be first estimated and then used as the initial guess, the algorithm tends to converge to the global solution more reliably and reconstruct high resolution. Examples include the “expanding Fourier modulus” method and ptychographic algorithms.

Partial Coherence Algorithms

The FT model in Eq. (1) assumes that the illumination beam is spatially and temporally fully coherent, which does not hold for many applications. Directly applying the coherent phase retrieval algorithm suffers from significant reconstruction artifacts in partially coherent CDI problem.

The diffraction intensity $I^{\text{PC}}(\mathbf{u})$ under partially coherent illumination is described through the mutual intensity function $J(\mathbf{r}_1, \mathbf{r}_2)$, which is a measure of the statistical correlations between a pair of points at $\mathbf{r}_1$ and $\mathbf{r}_2$ in the partially coherent field,

$$I^{\text{PC}}(\mathbf{u}) = \int \int J(\mathbf{r}_1, \mathbf{r}_2) g(\mathbf{r}_1) g^*(\mathbf{r}_2) \exp\{-i2\pi\mathbf{u} \cdot (\mathbf{r}_1 - \mathbf{r}_2)\} d^2\mathbf{r}_1 d^2\mathbf{r}_2 \quad (10)$$

The first approach to simplify Eq. (10) is to use the coherent mode decomposition model, which states that any partially coherent field can be decomposed into a set of coherent fields that are mutually incoherent,

$$J(\mathbf{r}_1, \mathbf{r}_2) = \sum_{n=1}^N \mu_n \psi_n(\mathbf{r}_1) \psi_n^*(\mathbf{r}_2) \quad (11)$$

The coherent modes are described by a set of orthonormal functions $\psi_n(\mathbf{r})$. The real, nonnegative number μ_n characterizes the amount of energy contained in each mode. Eq. (11) assumes that the majority of the energy in the illumination is contained in the first N modes. The diffraction intensity can be rewritten as

$$I^{\text{PC}}(\mathbf{u}) = \sum_{n=1}^N \mu_n \left| \int \psi_n(\mathbf{r}) g(\mathbf{r}) \exp\{-i2\pi\mathbf{u} \cdot \mathbf{r}\} d^2\mathbf{r} \right|^2 \quad (12)$$

which is the incoherent sum of the coherent diffraction intensities from the object illuminated with each coherent mode.

The second approach further assumes the illumination is statistically stationary and the mutual intensity function depends only on the spatial separations $\Delta \mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$. The diffraction intensity takes the following convolution form,

$$I^{\text{PC}}(\mathbf{u}) = \left| \int g(\mathbf{r}) \exp \{-i2\pi \mathbf{u} \cdot \mathbf{r}\} d^2 \mathbf{r} \right|^2 * S(\mathbf{u}) = I^{\text{C}}(\mathbf{u}) * S(\mathbf{u}) \quad (13)$$

where $I^{\text{C}}(\mathbf{u})$ is the intensity under coherent illumination; $S(\mathbf{u})$ is the FT of $J(\Delta \mathbf{r})$, which represents the intensity distribution of the primary source according to the Van Cittert–Zernike theorem.

When the coherence function of the illumination is known, the partially coherent phase retrieval can be achieved using a modified alternating projection algorithm that follows the similar four-step process. The only modification is to the second Fourier spectrum estimation step,

$$G'_s(\mathbf{u}) = G_s(\mathbf{u}) \cdot \sqrt{\frac{I(\mathbf{u})}{I_s^{\text{PC}}(\mathbf{u})}} \quad (14)$$

where $I_s^{\text{PC}}(\mathbf{u})$ denotes the estimated partially coherent diffraction intensity using either Eq. (12) or (13) in the s th iteration.

It has been shown heuristically that simultaneous recovery of the primary source (Eq. (13)) and the object function is possible from a single Fourier measurement and the object support constraint. The solution is found by solving the minimization problem,

$$\min_{\mathbf{g}, \mathbf{S}} \|\mathbf{I} - \mathbf{I}^{\text{C}} * \mathbf{S}\|_2^2 \quad (15)$$

where $\|\cdot\|_2^2$ represents the ℓ_2 norm of a vector, $\mathbf{g}$, $\mathbf{I}$, and $\mathbf{S}$ are vectors presenting the discretized object, intensity measurement, and source function, respectively. An alternating minimization strategy can be used that alternates between the two subproblems of coherent phase retrieval and source recovery in each iteration. The coherent phase retrieval can be implemented using any previous algorithm. The source is found by linear deconvolution assuming the coherent intensity is known. Since the full problem is nonlinear and nonconvex, the solution may still converge to a local minimum.

Three-Dimensional Recovery Problems

The 2D Fourier model in Eq. (1) relies on the assumption that the object is thin; the object function is determined by the projection approximation. When the object is thick and *weakly scattering*, the three-dimensional (3D) scattering process can be modeled using the first Born approximation, which accounts for only single scattering. The 3D CDI technique attempts to reconstruct the volumetric distribution of the object, which is characterized by the complex refractive index distribution $n(\mathbf{r}, z)$ as

$$g(\mathbf{r}, z) = \frac{\pi}{\lambda^2} (1 - n^2(\mathbf{r}, z)) \quad (16)$$

Denote the 3D FT of the object as $G(\mathbf{u}, w) = \mathcal{F}_{3D}\{g(\mathbf{r}, z)\}$, where w denotes the spatial frequency along the axis of illumination (z -axis). A single diffraction intensity $I(\mathbf{u})$ corresponds to a spherical cap on the Ewald sphere,

$$I(\mathbf{u}) = \left| G\left(\mathbf{u}, \sqrt{\frac{1}{\lambda^2} - |\mathbf{u}|^2} - \frac{1}{\lambda}\right) \right|^2 \quad (17)$$

To better cover the object's 3D Fourier space, diffraction data need to be collected at various orientations by either rotating the object or the illumination. In the reconstruction, alternating projection algorithms in Section Alternating Projection Algorithms have been extended to solve the 3D phase retrieval problem.

Defocus-Based Techniques

Defocus is another popular CDI method that is based on diffraction in free-space. The experimental procedure involves simply moving the camera (or the object) axially, while capturing multiple images through-focus, as illustrated in Fig. 3. The in-focus

Fig. 3 Schematics of defocus-based coherent diffractive imaging (CDI) techniques.

intensity image contains no phase information. The defocused intensity is characterized by the depth (z) dependent free-space point-spread-function (PSF) $h(\mathbf{r}, z)$. The measured intensity at z under coherent illumination is

$$I(\mathbf{r}; z) = \left| \int g(\mathbf{r}') h(\mathbf{r} - \mathbf{r}', z) d^2 \mathbf{r}' \right|^2 = |\mathcal{P}_z\{g\}|^2 \quad (18)$$

where $\mathcal{P}_z\{\cdot\}$ denotes the propagator at defocus distance z .

Many phase retrieval algorithms have been demonstrated for defocus measurements. The validity of each method depends on many experimental parameters, such as the defocus range, the object property, and the illumination coherence.

Iterative Algorithms

To solve the nonlinear Eq. (18), one can employ iterative algorithms. When only a single defocused intensity is available, the technique is also known as Fresnel CDI, which is analogous to the Fourier technique. All the iterative algorithms discussed in Section Fourier Measurement-Based Techniques can be applied by simply replacing $\mathcal{F}\{\cdot\}$ and $\mathcal{F}^{-1}\{\cdot\}$ by the (Fresnel) forward-propagator $\mathcal{P}_z\{\cdot\}$ and back-propagator $\mathcal{P}_z^{-1}\{\cdot\} = \mathcal{P}_{-z}\{\cdot\}$, respectively. All the limitations in the Fourier techniques still apply – the algorithm may stagnant and not converge due to the nonlinearity and nonconvexity.

In many practical applications, it is possible to take a series of defocused intensity measurement, $I(\mathbf{r}; z_m)$, $m=1, 2, \dots, M$. The most widely applied phase retrieval algorithm is the modified GS algorithm. In each iteration, one propagates the estimated field to each defocused planes, where the estimated amplitude is replaced by the measurement. To impose the amplitude constraints across multiple planes, two updating schemes have been implemented: sequential and global. The sequential GS algorithm imposes the amplitude constraint one plane at a time as the field propagates between the defocused and the object planes. The global GS algorithm instead updates the object field by averaging over estimates by imposing amplitude constraints from all defocused planes.

An alternative approach is based on solving the minimization of a cost function using the nonlinear optimization framework. For example, consider the amplitude-based least-square problem,

$$\min_{\mathbf{g}} E(\mathbf{g}) = \frac{1}{2} \sum_{m=1}^M \left\| \sqrt{\mathbf{I}_m} - |\mathbf{P}_{z_m} \mathbf{g}| \right\|_2^2 \quad (19)$$

where $\mathbf{g}$ and $\mathbf{I}_m$ are vectors presenting the discretized object function and intensity measurement at z_m , respectively. The discrete propagator $\mathbf{P}_{z_m}$ can be efficiently implemented using the fast Fourier transform (FFT), $\mathbf{P}_{z_m} = \mathbf{K}^H \mathbf{H}_{z_m} \mathbf{K}$, where $\mathbf{K}$ is the 2D discrete Fourier transform (DFT) matrix, $\mathbf{H}_{z_m} = \text{diag}(\exp[-i\pi\lambda z_m |\mathbf{u}|^2])$ is a diagonal matrix describing the Fresnel transfer function at the distance z_m , $\mathbf{u}$ is the discrete spatial frequency coordinates along the lateral dimensions, λ is the wavelength, $\text{diag}(\mathbf{a})$ denotes the diagonal matrix with its corresponding diagonal entries equal to the elements in the vector $\mathbf{a}$, and $\cdot^H$ denotes the matrix Hermitian. The back-propagation matrix $\mathbf{P}_{z_m}^{-1}$ satisfies $\mathbf{P}_{z_m}^{-1} = \mathbf{P}_{z_m}^H$, since $\mathbf{P}_{z_m}$ is unitary.

The reconstruction algorithm is then implemented following standard gradient-based optimization procedure. It starts with some initial guess of the object $\mathbf{g}_0$. At the s th iteration, the general equation for updating the object is

$$\mathbf{g}_{s+1} = \mathbf{g}_s + \alpha_s \mathbf{d}_s \quad (20)$$

where α_s is a step size, which can be a constant or found by a line-search algorithm. The search direction $\mathbf{d}_s$ is crucial for the algorithm convergence, which is determined by the gradient and/or second-order derivative (Hessian) of the cost function.

Both the gradient and Hessian can be conveniently calculated using $\mathbb{C}\mathbb{R}$ -calculus, in which the complex variable $\mathbf{g}$ is augmented as $[\mathbf{g}, \mathbf{g}^*]^T$ and $\bullet^*$ denotes the complex conjugate. The gradient of the cost function in Eq. (19) is

$$\nabla E(\mathbf{g}, \mathbf{g}^*) = \sum_{m=1}^M \begin{bmatrix} -\mathbf{P}_{z_m}^H \cdot \text{diag}(\mathbf{P}_{z_m} \mathbf{g} / |\mathbf{P}_{z_m} \mathbf{g}|) \\ -\mathbf{P}_{z_m}^T \cdot \text{diag}(\mathbf{P}_{z_m}^* \mathbf{g}^* / |\mathbf{P}_{z_m} \mathbf{g}|) \end{bmatrix} [\sqrt{\mathbf{I}_m} - |\mathbf{P}_{z_m} \mathbf{g}|] \quad (21)$$

where $\cdot^T$ denotes the matrix transpose.

In the first-order gradient descent (GD) methods, the search direction is simply the gradient of the cost function. In the second-order methods, the Hessian of the cost function $\nabla^2 E(\mathbf{g}, \mathbf{g}^*)$ is used to improve convergence speed. The search direction is then obtained by solving the linear equation

$$\nabla^2 E(\mathbf{g}, \mathbf{g}^*) \begin{bmatrix} \mathbf{d} \\ \mathbf{d}^* \end{bmatrix} = -\nabla E(\mathbf{g}, \mathbf{g}^*) \quad (22)$$

The Hessian matrix in practical phase retrieval problem is huge (size of N^2 , where N is the size of the object), so directly computing the inverse of Hessian is computationally prohibitive. Quasi-Newton's methods, such as the limited-memory Broyden-Fletcher-Goldfarb-Shanno method (L-BFGS) circumvents these problems by approximating the inverse of Hessian from the gradients of a few previous iterations. In modified Gauss-Newton methods, the inverse of Hessian is computed iteratively (e.g., using the conjugate gradient method) by solving the linear Eq. (22). Both the L-BFGS and modified Gauss-Newton methods have been applied to defocus phase retrieval problems and achieve better performance than the GS and GD algorithms.

Recursive Algorithms

The recursive algorithms, such as Kalman filter, attempts to progressively improve the phase estimate as each new intensity is included in the reconstruction. The intensity evolution upon propagation is treated with a complex augmented state space model. Denote the field at the m th plane and its FT as $\mathbf{a}_m$ as $\mathbf{b}_m$, respectively. Propagation of the intensity between consecutive defocus planes can be written in the Fourier domain as

$$\mathbf{b}_{m-1} = \mathbf{K}\mathbf{a}_{m-1} \quad (23)$$

$$\mathbf{b}_m = \mathbf{H}_m \mathbf{b}_{m-1} \quad (24)$$

where $\mathbf{H}_m$ is the matrix describing propagation by a distance $z_m - z_{m-1}$. The observation model assumes noisy intensity measurements,

$$\mathbf{I}_m = |\mathbf{a}_m|^2 + \mathbf{v}_m \quad (25)$$

where $\mathbf{v}_m$ assumes pixel-dependent gaussian noise with zero mean and a covariance matrix $\mathbf{R}_m \equiv \langle \mathbf{v}_m \mathbf{v}_m^T \rangle = \text{diag}(|\mathbf{a}_m|^2)$.

In the reconstruction, the Kalman filter phase retrieval (KF-PR) updates the estimates of both the field as well as its covariance matrix. The method is shown to be robust in the presence of significant noise corruption. The main computational requirement of KF-PR is the inversion of the covariance matrix. Sparsity priors in the covariance matrix have been exploited to significantly reduce the computational cost. Partial coherence KF-PR algorithm has also been demonstrated using the convolution model in Section Partial Coherence Algorithms.

Direct-Inversion Methods

When the object is weakly scattering in the sense of the first Born approximation being valid, and/or the defocus distance is small as compared to the Fresnel distance, the nonlinear measurement can be linearized, which allows implementations of direct-inversion algorithms. The transport of intensity equation (TIE) relates phase and amplitude to variations of intensity along the optical axis z ,

$$\frac{\partial I(\mathbf{r})}{\partial z} = -\frac{\lambda}{2\pi} \nabla_{\perp} \cdot [I(\mathbf{r}) \nabla_{\perp} \phi(\mathbf{r})] \quad (26)$$

where $I(\mathbf{r})$ is the intensity at focus, $\phi(\mathbf{r})$ is the phase, and $\nabla_{\perp}$ denotes the gradient operator in lateral directions $\mathbf{r}$ only. The problem is linear for small defocus distances.

Inversion algorithms for the TIE can be understood by considering the case of a pure-phase object, where $I(\mathbf{r})$ is constant. In this situation, the TIE simplifies to a Poisson equation, whose solution can be efficiently found by an FFT-based algorithm,

$$\phi(\mathbf{r}) = \mathcal{F}^{-1} \left\{ \mathcal{F} \left\{ \frac{2\pi}{\lambda I} \frac{\partial I(\mathbf{r})}{\partial z} \right\} / (4\pi^2 |\mathbf{u}|^2 + \delta) \right\} \quad (27)$$

The small regularization constant δ prevents instabilities around zero frequencies. When $I(\mathbf{r})$ is not constant, the inversion of the TIE requires solving two Poisson equations. The phase reconstruction algorithm does not require additional phase unwrapping step and is computationally efficient. In practice, one cannot measure intensity derivative directly and so it is usually estimated by finite difference methods. However, intensity is not linear upon propagation, which corrupts the derivative estimate. Higher-order TIE method has been demonstrated to mitigate this nonlinearity error by performing pixel-wise spatial domain polynomial fitting.

Contrast transfer function (CTF) is a linear model derived from the weak-object approximation,

$$g(\mathbf{r}) = \exp[-\alpha(\mathbf{r}) + i\phi(\mathbf{r})] \approx 1 - \alpha(\mathbf{r}) + i\phi(\mathbf{r}) \quad (28)$$

where $\alpha(\mathbf{r})$ characterizes the object's absorption. The FT of intensity at a distance z , $\mathcal{I}(\mathbf{u}; z)$ is linearly related to the FT of the phase $\Phi(\mathbf{u})$ and absorption $A(\mathbf{u})$ as

$$\mathcal{I}(\mathbf{u}; z) = \delta(\mathbf{u}) - 2A(\mathbf{u}) \cos(\pi\lambda|\mathbf{u}|^2 z) + 2\Phi(\mathbf{u}) \sin(\pi\lambda|\mathbf{u}|^2 z) \quad (29)$$

where $\delta(\mathbf{u})$ denotes the Dirac delta function.

The CTF suggests that the low-frequency phase information is only captured at large defocus distances. The intensity's FT follows a sinusoidal oscillation along the propagation direction with a frequency $\pi\lambda|\mathbf{u}|^2$, which increases as the spatial frequency becomes larger. The optimal design of defocus distances has shown to be exponentially spaced, which significantly reduces the number of images required to ensure high-quality phase recovery.

Phase reconstruction can be achieved by solving a linear deconvolution problem,

$$\min_{A, \Phi} \sum_m \sum_{\mathbf{u}} \left| \mathcal{I}(\mathbf{u}; z_m) - [\delta(\mathbf{u}) - 2A(\mathbf{u}) \cos(\pi\lambda|\mathbf{u}|^2 z_m) + 2\Phi(\mathbf{u}) \sin(\pi\lambda|\mathbf{u}|^2 z_m)] \right|^2 + \sum_{\mathbf{u}} [\alpha \|A(\mathbf{u})\|_2^2 + \beta \|\Phi(\mathbf{u})\|_2^2] \quad (30)$$

An alternative algorithm is based on pixel-wise spatial frequency domain curve-fitting to sinusoids. A Gaussian process regression-based method takes the CTF as the guideline to apply a thresholding operation in the curve-fitting process for suppressing the unwanted high frequency components in the fitted functions. The algorithm has been empirically shown to be robust even beyond the weak-object approximation, where the actual data deviates from the CTF model.

Transverse Translation-Based Techniques

The main limitation of the Fourier and defocus-based CDI techniques is the requirement of an isolated object. In the Fourier CDI technique, the size of the object cannot exceed the reciprocal of the detector's pixel size, due to the sampling requirement and Fourier transform relation between the object and image space. In the defocus based CDI technique, the object should be smaller than the detector. The transverse translation-based technique, commonly known as "ptychography," circumvents this problem by taking a series of Fourier diffraction images, while translating the illumination or the object, as illustrated in Fig. 4. A phase retrieval algorithm is then devised to *coherently* "stitch" all the intensity images from each sub field-of-view (FOV).

At the j th transverse position $\mathbf{r}_j$, the intensity $I_j(\mathbf{u})$ is simply the far-field diffraction of the exit wave from each sub-FOV, which can be modeled as the product of the object $g(\mathbf{r})$ with the shifted "probe" (illumination) function $p(\mathbf{r} - \mathbf{r}_j)$, assuming the object is thin,

$$I_j(\mathbf{u}) = \left| \int g(\mathbf{r}) p(\mathbf{r} - \mathbf{r}_j) \exp \{-i2\pi \mathbf{r} \cdot \mathbf{u}\} d^2 \mathbf{r} \right|^2 = |\mathcal{F}\{g(\mathbf{r}) p(\mathbf{r} - \mathbf{r}_j)\}|^2, \quad j = 1, 2, \dots, J \quad (31)$$

The phase retrieval algorithm reconstructs $g(\mathbf{r})$ from multiple intensity measurements at different probe positions. The success of this technique is highly dependent on the experimental parameters, such as the amount of overlap in the probe regions, the object property, and the illumination coherence. For example, a minimum of 60% of probe overlap has been reported both numerically and experimentally. It should be noted that even with the multiple intensity measurements, the underlying problem is still nonlinear and nonconvex, so the solution can get stuck in local minima. It has been shown empirically that transverse translation-based techniques significantly improve the convergence property, as compared to Fourier and defocused based techniques, because of the redundancy and diversity in the dataset.

Alternating Projection Algorithms

The most widely used ptychographic phase retrieval algorithm is based on the alternating projection framework. Similar to the modified GS algorithm in Section Iterative Algorithms, the multiple translational measurements can be processed using either the sequential or global scheme. The iterative algorithm allows simultaneous recovery of both the object and the probe functions.

The sequential algorithm is initialized with $g_0(\mathbf{r})$ and $p_0(\mathbf{r})$. In each iteration, it repeatedly applies two projection operations to each measurement one-by-one. In the j th subroutine within the s th iteration, it starts by calculating each exit field $\psi_{j,s}(\mathbf{r})$ from the j th sub-FOV,

$$\psi_{j,s}(\mathbf{r}) = g_{j,s}(\mathbf{r}) p_{j,s}(\mathbf{r} - \mathbf{r}_j) \quad (32)$$

The Fourier projection Π_F^S is applied to each exit field by imposing the amplitude constraint in two steps. It first replaces the Fourier magnitude by the measurement, while keeping the phase unchanged. An updated exit field, $\psi'_{j,s}(\mathbf{r})$ is then calculated by taking the inverse FT:

$$\Pi_F^S[\psi_{j,s}(\mathbf{r})] : \quad \Psi'_{j,s}(\mathbf{u}) = \mathcal{F}\{\psi_{j,s}(\mathbf{r})\} \cdot \frac{\sqrt{I_j(\mathbf{u})}}{|\mathcal{F}\{\psi_{j,s}(\mathbf{r})\}|} \quad (33)$$

$$\psi'_{j,s}(\mathbf{r}) = \mathcal{F}^{-1}\{\Psi'_{j,s}(\mathbf{u})\} \quad (34)$$

Next, the algorithm implements the overlap projection Π_O^S , which updates the object and probe functions:

$$\Pi_O^S[\psi_{j,s}(\mathbf{r})] : \quad g_{j+1,s}(\mathbf{r}) = g_{j,s}(\mathbf{r}) + \alpha \frac{p_{j,s}^*(\mathbf{r} - \mathbf{r}_j)}{|p_{j,s}(\mathbf{r})|_{\max}^2} [\psi'_{j,s}(\mathbf{r}) - \psi_{j,s}(\mathbf{r})] \quad (35)$$

Fig. 4 Schematics of transverse translation-based coherent diffractive imaging (CDI) techniques.

$$p_{j+1,s}(\mathbf{r}) = p_{j,s}(\mathbf{r}) + \beta \frac{g_{j,s}^*(\mathbf{r} + \mathbf{r}_j)}{|g_{j,s}(\mathbf{r})|_{\max}^2} \left[\psi'_{j,s}(\mathbf{r} + \mathbf{r}_j) - \psi_{j,s}(\mathbf{r} + \mathbf{r}_j) \right] \quad (36)$$

where α and β are step sizes and are often set to 1. The results are then used as the input to the $(j+1)$ th subroutine until all the diffraction intensities have been used.

In the global alternating projection scheme, the Fourier projection Π_F^G is accomplished by imposing all the amplitude constraints simultaneously to all the exit wave $\psi_s(\mathbf{r}) = (\psi_{1,s}(\mathbf{r}), \psi_{2,s}(\mathbf{r}), \dots, \psi_{j,s}(\mathbf{r}))$:

$$\Pi_F^G[\psi_s(\mathbf{r})] = \left(\Pi_F^S[\psi_{1,s}(\mathbf{r})], \Pi_F^S[\psi_{2,s}(\mathbf{r})], \dots, \Pi_F^S[\psi_{j,s}(\mathbf{r})] \right) \quad (37)$$

The overlap projection, Π_O^G , updates the object and probe functions by taking weighted averages:

$$\Pi_O^G[\psi_s(\mathbf{r})] : g_{s+1}(\mathbf{r}) = \frac{\sum_{j=1}^J p_s^*(\mathbf{r} - \mathbf{r}_j) \psi'_{j,s}(\mathbf{r})}{\sum_{j=1}^J |p_s(\mathbf{r} - \mathbf{r}_j)|^2} \quad (38)$$

$$p_{s+1}(\mathbf{r}) = \frac{\sum_{j=1}^J g_s^*(\mathbf{r} + \mathbf{r}_j) \psi'_{j,s}(\mathbf{r} + \mathbf{r}_j)}{\sum_{j=1}^J |g_s(\mathbf{r} + \mathbf{r}_j)|^2} \quad (39)$$

Other alternating projection algorithms, as introduced in Section Alternating Projection Algorithms, can also be applied. For example, the DM algorithm has been widely used in ptychographic phase retrieval and takes the following procedure to update the exit field,

$$\psi_{s+1}(\mathbf{r}) = \psi_s(\mathbf{r}) + \Pi_F^G[2\Pi_O^G[\psi_s(\mathbf{r})] - \psi_s(\mathbf{r})] - \Pi_O^G[\psi_s(\mathbf{r})] \quad (40)$$

Mode Multiplexing Algorithms

The redundancy and diversity in the ptychographic dataset makes it possible to recover additional information besides the object and probe functions. Consider applying the mode decomposition model (Eq. (11)) to both the probe and the object, the diffraction pattern at the j th transverse position is,

$$I_j(\mathbf{u}) = \sum_{n=1}^N \sum_{m=1}^M \left| \int g_{(m)}(\mathbf{r}) p_{(n)}(\mathbf{r} - \mathbf{r}_j) \exp \{-i2\pi \mathbf{r} \cdot \mathbf{u}\} d^2 \mathbf{r} \right|^2 = \sum_{n=1}^N \sum_{m=1}^M |\mathcal{F}\{g_{(m)}(\mathbf{r}) p_{(n)}(\mathbf{r} - \mathbf{r}_j)\}|^2, \quad j = 1, 2, \dots, J \quad (41)$$

where $g_{(m)}(\mathbf{r})$ is the m th mode of the object and $p_{(n)}(\mathbf{r})$ the n th mode of the probe.

The alternating projection algorithms can be extended to the mode decomposition problem to simultaneously reconstruct the M mutually incoherent object modes and the N mutually incoherent probe modes. Each iteration starts by calculating the $M \times N$ coherent exit field from all possible pairs of the object and probe modes,

$$\psi_{(m,n)}(\mathbf{r}) = g_{(m)}(\mathbf{r}) p_{(n)}(\mathbf{r} - \mathbf{r}_j) \quad (42)$$

The Fourier and overlap projections are then applied similar to the coherent case. In the sequential scheme, the Fourier update Eq. (33) is replaced by

$$\Psi'_{(m,n),j,s}(\mathbf{u}) = \mathcal{F}\{\psi_{(m,n),j,s}(\mathbf{r})\} \cdot \frac{\sqrt{I_j(\mathbf{u})}}{\sqrt{\sum_{n=1}^N \sum_{m=1}^M |\mathcal{F}\{\psi_{(m,n),j,s}(\mathbf{r})\}|^2}} \quad (43)$$

which is applied to all the exit field. The rest of the steps follow the same operations as described in Eqs. (34–36), which are applied simultaneously to each exit wave.

The global scheme makes the same modifications to the Fourier projection as the sequential scheme. The overlap projection updates all the object and probe modes by taking the weighted average over all the modes and measurements,

$$g_{(m)s+1}(\mathbf{r}) = \frac{\sum_{j=1}^J \sum_{n=1}^N p_{(n)s}^*(\mathbf{r} - \mathbf{r}_j) \psi'_{(m,n),j,s}(\mathbf{r})}{\sum_{j=1}^J \sum_{n=1}^N |p_{(n)s}(\mathbf{r} - \mathbf{r}_j)|^2} \quad (44)$$

and

$$p_{(n)s+1}(\mathbf{r}) = \frac{\sum_{j=1}^J \sum_{m=1}^M g_{(m)s}^*(\mathbf{r} + \mathbf{r}_j) \psi'_{(m,n),j,s}(\mathbf{r} + \mathbf{r}_j)}{\sum_{j=1}^J \sum_{m=1}^M |g_{(m)s}(\mathbf{r} + \mathbf{r}_j)|^2} \quad (45)$$

The general mode decomposition model above has been applied to various situations. The probe mode decomposition model is useful to account for the effects of partially coherent illumination. A major limitation of ptychography is the long acquisition time required to collect all the images. “Fly-scan” ptychography attempts to improve the data collection speed by continuously scanning the probe during the exposure time. It has been shown that the motion blurs in fly-scan measurements can be accounted for using the probe mode decomposition model. Multi-spectral and polarization multiplexed ptychographic measurements have been attempted. Spectrally and polarization resolved reconstructions have been demonstrated by adapting the mode multiplexing algorithms to the problem of decomposing both the object and probe by their respective spectral and polarization channels.

Fig. 5 Schematics of the multi-slice ptychography.

Multi-Slice Algorithms

The multiplicative model used in 2D ptychography breaks down when the object is thick and multiple scattering effects become nonnegligible. The multi-slice model is proposed to extend the depth of field and partially accounts for the forward multiple scattering effects.

A thick object is modeled as M thin slices, each described by a transmittance function $g^{(m)}(\mathbf{r})$ ($m = 1, 2, \dots, M$) (Fig. 5). The layer in-between is assumed uniform (e.g., air) of thickness Δz_m . The exit field from the object is modeled by a series of multiply-and-propagate operations,

$$\psi_j(\mathbf{r}) = \mathcal{P}_{\Delta z_{M-1}} \left\{ \dots \mathcal{P}_{\Delta z_2} \left\{ \mathcal{P}_{\Delta z_1} \left\{ p_j(\mathbf{r} - \mathbf{r}_j) g^{(1)}(\mathbf{r}) \right\} g^{(2)}(\mathbf{r}) \right\} \dots \right\} g^{(M)}(\mathbf{r}) \quad (46)$$

where the propagator can be computed using the angular spectrum method, $\mathcal{P}_{\Delta z}\{\cdot\} = \mathcal{F}^{-1} \left\{ \exp \left[i 2 \pi \Delta z \sqrt{1/\lambda^2 - |u|^2} \right] \mathcal{F}\{\cdot\} \right\}$. After passing through the object, the far-field diffraction intensity is measured,

$$I_j(\mathbf{u}) = |\mathcal{F}\{\psi_j(\mathbf{r})\}|^2 \quad (47)$$

The reconstruction algorithm can be implemented by extending the sequential 2D alternating projection algorithm to accounting for the multi-slice model. The j th subroutine within the s th iteration starts with the estimated j th exit field $\psi_{j,s}(\mathbf{r})$. Next, the Fourier projection is applied to update the exit field,

$$\psi'_{j,s}(\mathbf{r}) = \prod_{\mathbf{F}}^S [\psi_{j,s}(\mathbf{r})] \quad (48)$$

To update each object slice, the algorithm then recursively applies the “overlap-projection back-propagation” operation until the first slice is reached. The incident field $\phi_{j,s}^{(m)}(\mathbf{r})$ and the exit field $\psi_{j,s}^{(m)}(\mathbf{r})$ for the m th slice is related by

$$\psi_{j,s}^{(m)}(\mathbf{r}) = \phi_{j,s}^{(m)}(\mathbf{r}) g_{j,s}^{(m)}(\mathbf{r}) \quad (49)$$

Eq. (49) takes the same form as Eq. (32), except for the coordinate change. As a result, the overlap projection operation in 2D ptychography can be easily extended here. The modified overlap projection $\prod_{\mathbf{O}}^{S'}$ essentially separates the field scattered from the current slice from the field scattered from all previous slices,

$$\prod_{\mathbf{O}}^{S'} [\psi_{j,s}^{(m)}(\mathbf{r})] : g_{j+1,s}^{(m)}(\mathbf{r}) = g_{j,s}^{(m)}(\mathbf{r}) + \alpha \frac{\phi_{j,s}^{(m)*}(\mathbf{r})}{|\phi_{j,s}^{(m)}(\mathbf{r})|_{\max}^2} [\psi_{j,s}^{(m)'}(\mathbf{r}) - \psi_{j,s}^{(m)}(\mathbf{r})] \quad (50)$$

$$\phi_{j,s}^{(m)'}(\mathbf{r}) = \phi_{j,s}^{(m)}(\mathbf{r}) + \beta \frac{g_{j,s}^{(m)*}(\mathbf{r})}{|g_{j,s}^{(m)}(\mathbf{r})|_{\max}^2} [\psi_{j,s}^{(m)'}(\mathbf{r}) - \psi_{j,s}^{(m)}(\mathbf{r})] \quad (51)$$

The back-propagation operation is then applied to update the exit field of the $(m-1)$ th slice,

$$\psi_{j,s}^{(m-1)'}(\mathbf{r}) = \mathcal{P}_{\Delta z_{m-1}}^{-1} \left\{ \phi_{j,s}^{(m)'}(\mathbf{r}) \right\} \quad (52)$$

At the first slice, the overlap projection of 2D ptychography is applied to update the object slice and the probe functions: $\prod_{\mathbf{O}}^S [\psi_{j,s}^{(1)}(\mathbf{r})]$.

Illumination Angle Scanning-Based Fourier Ptychography

Fourier ptychography (FP) is a computational microscopy technique that achieves gigapixel imaging capability with both wide FOV and high resolution in both phase and amplitude. The working principle of FP can be understood as the implementation of the regular ptychography in the Fourier conjugate planes. The setup involves scanning the illumination across different angles, as illustrated in (Fig. 6).

Consider a thin sample with transmission function $g(\mathbf{r})$. The object is illuminated by a plane wave with the spatial frequency $\mathbf{u}_\ell$, defined by $\exp(i 2 \pi \mathbf{u}_\ell \cdot \mathbf{r})$. After passing through the object, the exit wave is the product of the object and the illumination,

Fig. 6 Schematics of Fourier ptychography.

$g(\mathbf{r}) \exp(i2\pi\mathbf{u}_\ell \cdot \mathbf{r})$. In the Fourier space, this corresponds to a shifted version of the Fourier spectrum of the object, $G(\mathbf{u} - \mathbf{u}_\ell)$, where $G(\mathbf{u}) = \mathcal{F}\{g(\mathbf{r})\}$. This Fourier spectrum is then low-pass filtered by the pupil function, $P(\mathbf{u})$. The final intensity taken by the real-space camera is

$$I_\ell(\mathbf{r}) = |\mathcal{F}\{P(\mathbf{u})O(\mathbf{u} - \mathbf{u}_\ell)\}|^2 \quad (53)$$

The goal of the FP algorithm is to stitch together all the diffraction intensity corresponding to different areas of Fourier space in order to increase the bandwidth/resolution of the final image. The effective numerical aperture (NA) is the sum of the objective NA and illumination NA. Similar to the regular ptychography, phase is necessary to *coherently* combine all the intensity images. The first FPM algorithm adapted the sequential alternating projection algorithm in the regular ptychography. Shifted support constraints from the finite pupil size are enforced in the Fourier domain and the corresponding amplitude constraints (measured images) are applied in the real space, while letting the phase evolve as each image is stepped through sequentially.

Significant progress has been made to extend the various schemes in the regular ptychography to FP. The recovery of the aberration in the pupil function is demonstrated by adapting the probe recovery algorithm. FP mode multiplexing algorithms have been developed to allow reconstruction using much fewer images by simultaneously illuminating the object from multiple mutually incoherent illumination beams when capturing each image, as well as to recover spectrally multiplexed information. FP multi-slice algorithm has been developed to recover 3D object and improve spatial resolution in all three dimensions.

Phase Space and Imaging

Introduction

Phase-space optics (Torre, 2005) represents a framework to model optical systems and signal propagation. It introduces concepts of joint time-frequency transforms, well established for signal processing, to the domain of ray and wave optics. In contrast to many joint transforms specifically designed for signal processing applications, phase-space optics preserves a physical interpretation of the joint space – spatial frequency representation. In close analogy to the phase space of classical and quantum mechanics, the physics of optical signal propagation is encoded in the associated phase-space representation.

Optical system analysis and design usually avoid rigorous modeling of Maxwell's equations. Instead, convenient approximations are in use, which are tailored to the typical constraints of optical systems. These include ray optics and radiometry, Gaussian beam optics, Fourier optics of scalar complex amplitudes, as well as coherence theory. Phase-space optics combines most aspects of the aforementioned into a single signal representation. This is particularly true for paraxial signals and systems, where formal relationships or even the equivalence of models can be established rather straightforwardly.

This article surveys the application of phase-space optics to optical imaging. While phase-space optics may be developed as a consistent replacement of more common models of light propagation, it is generally more useful to consider it as a complementary framework, which can be used to find solutions to specific imaging related problems more easily. This refers in particular to problems involving the analysis of the space-bandwidth requirements of signals and systems. For phase imaging phase-space optics provides a unique perspective, which has motivated new signal recovery methods, namely phase-space tomography. The phase-space interpretation provides a unique platform to compare imaging modalities and to establish performance limits. Furthermore, the phase space of quasi-geometrical optics establishes highly intuitive interpretations for optical problems otherwise burdened with the overhead of mathematical formalism.

Elements of Phase Space Optics

Optical phase space may be introduced conveniently as the configuration space of generalized ray coordinates. This means, in each plane along the optical axis z , any optical ray is characterized by its transverse location x and its angle of propagation θ relative to the optical axis. Each pair of generalized coordinates corresponds to a single point in phase space. It is often convenient to associate the propagation direction of a ray with the spatial frequency $v = \sin(\theta)/\lambda$ of a coherent monochromatic plane wave propagating in the same direction, thereby associating the spatial frequency effectively with a bundle of parallel rays.

Consequently, the phase-space distribution of rays $W(x, v)$ obeys the rules of paraxial ABCD matrix optics (Saleh and Teich, 1991). This is, for a paraxial optical system, the input ray coordinates (x_{in}, v_{in}) are related to the output coordinates (x_{out}, v_{out}) by the system's ray transfer matrix,

$$\begin{pmatrix} x_{out} \\ v_{out} \end{pmatrix} = \begin{pmatrix} A & B \\ C & D \end{pmatrix} \begin{pmatrix} x_{in} \\ v_{in} \end{pmatrix} \quad (1)$$

with the shape of the phase-space distribution transforming accordingly,

$$W_{out}(x, v) = W_{in}(Dx - Bv, -Cx + Av) \quad (2)$$

If the input and the output plane of the system are located in a medium of the same refractive index, the determinate of the ray-transfer matrix is always equal to one, i.e., only three of the four matrix coefficients are independent.

For three-dimensional geometries, both x and v are two-dimensional vectors. The phase-space distribution $W(x, v)$ may be recognized as the radiance, i.e., the power directed along v and radiating from, or being received by a point x .

For partially coherent optical signals the concept of radiance may be generalized and the phase-space distribution is defined as the Fourier transform of the cross spectral density $J(x_1, x_2)$ (see chapters 1, 2 and 7 of Testorf *et al.*, 2009),

$$W(x, v) = \int_{-\infty}^{\infty} J(x + x'/2, x - x'/2) \exp(-i2\pi x'v) dx' \quad (3)$$

For the ideal case of incoherent signals, the phase space distribution is given by the irradiance distribution,

$$W(x, v) = I(x) \quad (4)$$

For coherent wavefronts, the mutual intensity factorizes and the phase-space distribution becomes the Wigner distribution function (WDF) of the complex amplitude $u(x)$,

Fig. 1 Phase-space diagrams of ray transformations: (a) Phase-space diagram of a generic signal with essential support Δx and essential bandwidth $\Delta \nu$. (b) Phase-space distribution of the signal in (a) after Fresnel diffraction, (c) transmission through a thin paraxial lens, and (d) after Fourier transformation of the signal. Corners of the phase-space volume are numbered to depict the orientation of the transformed volume.

$$W(x, \nu) = \int_{-\infty}^{\infty} u\left(x + \frac{x'}{2}\right) u^*\left(x - \frac{x'}{2}\right) \exp(-i2\pi \nu x') dx' \quad (5)$$

As long as diffracting system apertures can be ignored, the ABCD transfer matrix equally applies to all definitions of $W(x, \nu)$. This implies, that the dynamics of coherent and partially coherent signals can be associated with geometrical transformations of phase space. For instance, free space propagation corresponds to a shear of phase space parallel to the spatial axis, and the transfer matrix of Fresnel diffraction reads

$$\mathbf{T}_f = \begin{pmatrix} 1 & \lambda z \\ 0 & 1 \end{pmatrix} \quad (6)$$

where z is the propagation distance. A thin parabolic lens of focal length f is given by

$$\mathbf{T}_l = \begin{pmatrix} 1 & 0 \\ -\frac{1}{\lambda f} & 1 \end{pmatrix} \quad (7)$$

which is equivalent to a chirp modulation of the complex amplitude.

A Fourier transform step is equivalent to a rotation of phase space by 90° , and consequently, a 2-f system corresponds to a combination of 90° rotation and a magnification step. Rotation with arbitrary angles correspond to fractional Fourier transforms of the signal (Ozaktas *et al.*, 2001).

Fig. 1 depicts a set of the generic phase-space transformations in the form of phase-space diagrams. Signals are schematically represented by a finite phase-space volume with extensions equivalent to the essential signal support and bandwidth. This identifies the phase-space volume as a measure of the space-bandwidth product of the signal.

In the context of optical imaging it is important to highlight a number of properties of the WDF. The WDF is a real valued function. It is symmetric with respect to the two variables x and ν , and we find the alternative definition,

$$W(x, \nu) = \int_{-\infty}^{\infty} \tilde{u}\left(\nu + \frac{\nu'}{2}\right) \tilde{u}^*\left(\nu - \frac{\nu'}{2}\right) \exp(i2\pi \nu' x) d\nu' \quad (8)$$

with $\tilde{u}(\nu)$ being the Fourier transform of the signal

$$\tilde{u}(\nu) = \int_{-\infty}^{\infty} u(x) \exp(-i2\pi \nu x) dx \quad (9)$$

was used. The WDF is a complete signal representation in so far as the complex amplitude can be recovered from the WDF except for a constant phase factor. Intensity and power spectrum of the complex signal are calculated as projections of the WDF,

$$\int_{-\infty}^{\infty} W(x, \nu) d\nu = |u(x)|^2 \quad \text{and} \quad \int_{-\infty}^{\infty} W(x, \nu) dx = |\tilde{u}(\nu)|^2 \quad (10)$$

The WDF is a bilinear transformation of $u(x)$. This means, the sum of two signals will be transformed into the respective WDFs, with additional interference or cross terms added. For instance, a signal consisting of two plane waves, $u_{1,2}(x) = \exp(i2\pi v_1 x) + \exp(i2\pi v_2 x)$, is transformed into

$$W_{1,2}(x, v) = \delta(v - v_1) + \delta(v - v_2) + 2\cos[2\pi(v_1 - v_2)]\delta\left(v - \frac{v_1 + v_2}{2}\right) \quad (11)$$

The WDF contains a frequency, which is located halfway between the two plane wave frequencies, and which is modulated by a cosine function. The modulation frequency of the interference term reflects the spacing between the unmodulated frequency terms. This interference term effectively encodes the mutual coherence of the two plane waves.

The convolution of two signals,

$$u_c(x) = u_1(x) * u_2(x) \quad (12)$$

is transformed into a convolution of the respective WDFs with respect to x and a multiplication with respect to v ,

$$W_c(x, v) = W_1(x, v) *_x W_2(x, v) \quad (13)$$

Similarly, a multiplication of two signals, i.e., a convolution in the frequency domain, is transformed into a convolution of the WDFs with respect to v ,

$$W_M(x, v) = W_1(x, v) *_v W_2(x, v) \quad (14)$$

For slowly varying phase functions, $u(x) = \exp(i\phi(x))$, the WDF can be approximated by the instantaneous (or local) frequency of the signal,

$$W_u(x, v) \approx \delta\left(v - \frac{1}{2\pi} \frac{d\phi(x)}{dx}\right) \quad (15)$$

which may be interpreted as the quasi-geometrical approximation of WDF. For quadratic phase functions, Eq. (15) is the exact expression for the WDF, which is equivalent to an inclined line in phase space.

The WDF is related to the ambiguity function (AF) (chapter 2 of Testorf *et al.*, 2009) via a double Fourier transformation,

$$A(\bar{v}, \bar{x}) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} W(x, v) \exp[-i2\pi(\bar{v}x - \bar{x}v)] dx dv \quad (16)$$

Many of the properties of the WDF carry over to the AF domain, namely the ray matrix transformation to relate input and output AF for quadratic phase systems.

Phase-Space Interpretation of Image Formation

In classical geometrical optics, perfect imaging is accomplished, if all rays originating from one point in the object plane intersect in a single point in the imaging plane. The spatial coordinates of object and image points are relate by a constant magnification factor, i.e.,

$$x_{out} = m x_{in} \quad (17)$$

Negative magnification refers to an inverted image.

In phase space, the set of all rays crossing through a single point in space define a line parallel to the frequency axis (Fig. 2). This implies that perfect imagery is accomplished with optical systems, which map vertical lines in phase space to vertical lines with a constant scaling factor in x .

This implies a ray transfer matrix with $A=m$ and $B=0$ and $D=1/m$. The forth parameter C can be chosen freely to satisfy the imaging condition. This matrix can be interpreted as a magnification step followed by a chirp modulation, i.e.,

$$\begin{pmatrix} m & 0 \\ C & 1/m \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ C & 1 \end{pmatrix} \begin{pmatrix} m & 0 \\ 0 & 1/m \end{pmatrix} \quad (18)$$

While coefficient $A=m$ represents the spatial magnification factor of the imaging system, $D=1/m$ is the angular magnification factor.

This is exemplified by a single lens system, consisting of free space propagation over a distance a , a lens of focal length f , followed by propagation over a distance b , with the additional condition $1/f = 1/a + 1/b$. The associated transfer matrix reads

$$\mathbf{T}_{SLI} = \begin{pmatrix} 1 & \lambda b \\ 0 & 1 \end{pmatrix} \begin{pmatrix} 1 & 0 \\ -1/\lambda f & 1 \end{pmatrix} \begin{pmatrix} 1 & \lambda a \\ 0 & 1 \end{pmatrix} = \begin{pmatrix} -\frac{b}{a} & 0 \\ -\frac{1}{\lambda f} & -\frac{a}{b} \end{pmatrix} \quad (19)$$

The case $C=0$ describes an afocal imaging system. A parallel bundle of input rays is transformed into a parallel bundle of output rays. The 4-f system and the closely related Kepler telescope are particular examples of afocal systems.

Fig. 2 Single lens imaging: (a) Phase-space diagram of input signal; (b) phase-space distribution in the image plans.

For $C \neq 0$ the chirp modulation corresponds to a shear of the phase-space distribution along the frequency axis (**Fig. 2(b)**). For the ideal case of a strictly incoherent object, with $W(x, \nu) = I(x)$, the phase space distribution is shift-invariant with respect to frequency and the vertical shear is not encoded in the phase space of the image plane. For the more general case of partially coherent or coherent signals, the shear of the phase space distribution corresponds to a modulation of the wavefront with a quadratic phase function.

For a wave optical analysis and finite lens apertures, the WDF of the aperture is convolved in ν with the signal's WDF in the aperture plane and further propagated to the output plane.

Imaging Aberrations

The close relationship between geometrical optics and phase space extends beyond the paraxial regime, and the phase-space formalism inherently is an integral part of geometrical optics theory (Wolf, 2004). This includes the analysis of optical aberrations.

One approach to understand imaging aberrations in the context of optical phase space is the interpretation of geometrical aberrations as deviations from the linear transformation, which connects input and output of the imaging systems. This means, the generalized coordinates of the output ray are no longer linear functions of the input coordinates expressed by a ray transfer matrix with constant coefficients. Instead, the matrix coefficients are functions of the input ray coordinates and the phase space distribution is distorted in both x and ν coordinate. As a consequence, the image, i.e., the projection of the phase space distribution along ν in the output plane of the system, is not longer a perfect copy of the object.

This nonlinear geometrical transform of phase space can be reversed, if the phase space distribution is known. This forms the basis for aberration correction with lightfield camera systems (see Section Lightfield Imaging).

The interpretation of aberrations as a geometrical distortion of phase space can be translated to the analysis of wavefront aberrations and their influence on the WDF of the optical signal. Wave aberrations may be interpreted as a phase-only modulation of the wavefront in the exit pupil of the imaging system. The phase $\phi(x)$ can be expressed as a power series and for a smooth aberration function the WDF of the modulating function can be approximated by the local frequency (Lohmann *et al.*, 1983),

$$W_{ab}(x, \nu) \approx \delta \left[\nu - \frac{1}{2\pi} \frac{\phi(x)}{dx} \right] \quad (20)$$

The aberrated phase space distribution is the result of a convolution of $W_{ab}(x, \nu)$ with the WDF of the ideal wavefront in ν in the plane of the exit pupil. This is identical with a local shift of the WDF along the frequency axis and proportional to the local frequency.

In the image plane, the WDF of the exit pupil appears essentially rotated due to the inherent Fourier relationship between exit pupil and image plane, and the aberrations are manifest as frequency dependent shifts along the x axis. Consequently, image points derived as the projection of the output WDF are blurred compared to the non-aberrated image point.

The Self-Imaging Condition

The phase space analysis of classical geometric optical imaging suggests generalizations imaging. The point-to-point mapping of optical rays and the associated mapping of vertical lines in phase space implies a mapping of the irradiance distribution, i.e., the imaging system is designed to reproduce the vertical projection of phase space. For incoherent imaging this reproduces all information available about the object.

For imaging applications based on coherent optical signals, it is equally possible to associate imaging with a recovery of the complex amplitude, equivalent to a full recovery of the object's phase space distribution. Furthermore, neither the recovery of the actual phase space distribution, nor its projection needs to be the result of a spatial point-to-point mapping of the signal. Instead, each image point may be assembled as an interference pattern of signals originating from more than one single object point.

The latter cannot be ensured to work for arbitrary objects, but rather limits imaging for a particular system to a subset of all possible objects.

One example of this type of imaging is the Talbot effect, also known as coherent self-imaging. In its most generic form, self-images is associated with Fresnel diffraction of periodic object waves. Images, i.e., replica of the complex amplitude of the object are observed at multiples of the Talbot distance,

$$z_T = \frac{2p^2}{\lambda} \quad (21)$$

where p is the transverse period of the object wave.

In phase space the coherent periodic signal corresponds to a WDF, which is periodic in x and discrete in frequency ν (Fig. 3(a)). In particular, for signals of the form,

$$u(x) = u(x - p) = \sum_{n=-\infty}^{\infty} a_n \exp(i2\pi x n/p) \quad (22)$$

the WDF reads,

$$W(x, \nu) = W(x - p, \nu) = \sum_{n, n'=-\infty}^{\infty} a_n a_{n'}^* \exp(i2\pi x(n - n')/p) \delta\left(\nu - \frac{n + n'}{2p}\right) \quad (23)$$

Due to cross-terms the spacing of the discrete frequencies is $\Delta\nu = 1/(2p)$.

Fresnel diffraction corresponds to a linear shear (Fig. 3(b)). The sheared WDF is identical to the initial distribution, when the lowest non-zero frequency component is shifted by p , or

$$\lambda z_T \frac{1}{2p} = p \quad (24)$$

which effectively provides a geometrical derivation of the Talbot distance (see chapter 10 of Testorf *et al.*, 2009).

The self-imaging principle can easily be generalized to account for image magnification, and other optical systems, which restore the WDF of particular types of signals (Testorf and Hennelly, 2016). Most interestingly, the phase-space interpretation highlights the duality between operation in the spatial and the spatial frequency domain. This means, for instance, the Talbot effect has a dual frequency counterpart, which is equivalent to modulating a discrete signal with a quadratic phase function. In phase-space, space and spatial frequency axis are merely two particular orientations and self-imaging can be further generalized to include discrete chips which are sheared along their axis of orientation in phase space.

Holographic Imaging

The phase-space formulation of holographic imaging provides an intuitive interpretation of critical properties, namely the space-bandwidth product requirements of the recording medium and conditions for a unique recovery of the wavefront during the reconstruction step (Lohmann *et al.*, 2004).

The phase-space analysis of the holographic principle can be demonstrated by assuming a wavefront in the recording plane composed of the complex amplitude of the object wave $u(x)$ and a plane off-axis reference wave. Fig. 4(a) schematically depicts the object wave O and the off-axis plane wave R in the recording plane. The reference wave corresponds to a line parallel to the x axis. The extensions in space Δx and frequency $\Delta\nu$ define the space-bandwidth product (SBP) of the object wave. The spatial frequency of the reference wave is ν_R . The phase-space diagram in Fig. 4 does not contain any cross-terms, since they are inconsequential for the interpretation of the holographic principle that follows.

Fig. 3 Selfimaging in phase-space: (a) Phase-space diagram of periodic signal. The diagram depicts a finite number of periods and harmonics only. The vertical dashed lines mark arbitrary locations x ; (b) phase-space distribution after Fresnel diffraction over a single Talbot length.

Fig. 4 Holography in phase space: (a) Phase-space diagram of the signal O and the plane reference wave R . (b) Phase-space distribution after the recording. The hologram is composed of the object O , the autocorrelation of object A_O and reference A_R , as well as the twin image T .

The holographic recording stores the squared magnitude of the complex amplitude, i.e., the transmission function of the recorded hologram reads

$$t(x) = |u(x) + \exp(i2\pi v_R x)|^2 = (1 + |u(x)|^2) + u^*(x)\exp(i2\pi v_R x) + u(x)\exp(-i2\pi v_R x) \quad (25)$$

with last term containing the object wave.

In phase space, the squared modulus of a signal is translated into the autocorrelation function of the WDF along v . The autocorrelation of object wave A_O and reference A_R are centered at the origin in phase space (Fig. 4(b)). Apart from the object wave O it is possible to observe the twin image T . All terms occupy separate volumes and do not overlap. This is necessary to recover and isolated the object term by illuminating the hologram with the reference wave. Estimating the bandwidth of the autocorrelation term to be twice the bandwidth of the object, the minimum frequency of the reference wave has to be

$$v_R \geq \frac{3}{2} \Delta v \quad (26)$$

The bandwidth of the hologram equals $2v_R + \Delta v$, which is at least four times the bandwidth of the hologram.

Fig. 4(b) can be interpreted as the phase-space diagram of image plane holography or Fourier plane holography. For the latter case, object wave and reference are recorded after a Fourier transform step equivalent to a 90° rotation of phase space. For Fresnel plane holography, the object wave is propagated in free space before it is recorded. The corresponding phase space operation is a horizontal shear, and it is possible to derive the SBP requirements of the recording medium from a geometric interpretation in phase space (Lohmann *et al.*, 2004).

Instead of analysing holography exclusively in the WDF domain, it is possible to use the AF (Situ and Sheridan, 2007). The AF of the complex amplitude may be interpreted as a generalized autocorrelation function. This means, the phase-space diagram of the AF of the complex amplitude resembles the diagram of the WDF of the recorded signal in Fig. 4(b). The actual transmission function of the hologram can be identified as the Fourier transform of the cross-section of the AF along its frequency axis.

Lightfield Imaging

The lightfield is closely related to the phase space of geometrical optics. Instead of parameterizing rays in each plane along the optical axis by their transverse location and propagation direction, the lightfield defines each ray by its spatial coordinates in two planes. While encoding the ray parameters in a different way, the lightfield and geometrical optical phase space contain the same information about the optical signal. Lightfield imaging is aimed at sampling the lightfield (or phase space) of the signal directly, rather than its projections.

This may be accomplished with a lightfield (or plenoptic) camera. The most generic implementation of the plenoptic camera is based on Lippmann's concept of integral photography. The detector array in the image plane of a camera system is replaced with a lenslet array and the detector, now located in the focal plane of the lens array (Fig. 5(a)). The aperture Δx of each lenslet defines the spatial resolution of the image as well as the spatial resolution with which phase space is sampled. The propagation direction of the ray is encoded as lateral displacement in the detector plane. Consequently, with the framework of geometrical optics, the angular resolution is determined by the pixel size Δx_θ , with an angular resolution $\Delta\theta \approx \Delta x_\theta/f$ and the resolution in frequency estimated as $\Delta v \approx \Delta x_\theta/(\lambda f)$.

This means, each detector pixel corresponds to a finite area in phase-space. The center of this finite volume in phase space indicates the position of the microlens. Each microlens projects the signal onto a subset of detector elements each in turn encoding a location along the frequency direction.

The phase-space diagram of the focal plane array is rendered in Fig. 5(b). Each ellipse schematically depicts the footprint of a single detector element. The recorded signal is the average of the signal's phase-space distribution over the volume covered by a

Fig. 5 Lightfield detector: (a) a focal plane array can be used to measure the radiance distribution. (b) The phase-space diagram of the focal plane array. Each ellipse corresponds to the phase-space volume recorded by a single detector element.

Fig. 6 Phase-space diagram of the focal plane array for correcting defocus: Each detector in phase space is associated with the location the in-focus phase-space distribution would assume in an out-of-focus plane. The in-focus image can be recovered by numerically reassigning the position of the detected phase-space locations before rendering the image from the frequency projection.

detector element. This means, as long as the phase-space distribution changes slowly on the scale of the detector's phase-space coverage, the focal plane array can be used as a phase-space detector without loss of important information. The number of detectors is equivalent to the SBP of the camera, i.e., comparing this with the SBP of the signal allows an estimation of how well the lightfield camera is recording the signal information.

Direct access to the phase-space distribution allows one to transform phase space before rendering an image by projecting along the frequency axis. This permits a change of perspective, refocusing, as well as the compensation of aberrations after recording a single lightfield. For instance, to correct defocus the signal associated with a detector is assigned to a point in phase space, which reflects the geometrical transform of phase space associated with free space propagation (Fig. 6). The defocus blur can be removed by reassigning the phase-space coordinates to the locations of the in-focus plane in Fig. 5(b), which is equivalent to rendering the image from projections at the shear angle.

The lightfield concept can also be used to design three-dimensional displays for autostereoscopic viewing. This can be understood as reversing the recording process, i.e., each pixel of the detector is replaced with a point source. This creates a virtual image, which is viewed through the lenslet array. Each of the point sources encodes one sample of the radiance distribution of the reconstructed optical signal.

The lightfield inherently assumes a geometrical optics model of imaging with a phase-space distribution that is changing slowly. In this context, the focal plane array provides sufficient information to determine the radiance distribution from the recorded samples. If diffraction effects have to be accounted for the finite phase-space volume of a single detector does not provide sufficient resolution of phase space and it is necessary to recover the actual WDF of the optical signal. In general, it is necessary to resort to a synthesis of the phase-space distribution from information acquired with multiple recordings in different diffraction planes.

Phase-Space Tomography and Phase Retrieval

Every measurement in the optical regime can be interpreted as a power reading written as a projection

$$P = |\langle u(x), h(x) \rangle|^2 \quad (27)$$

where the complex amplitude $u(x)$ is detected with an optical instrument $h(x)$. This formalism, for instance, describes the coupling of the coherent wavefront $u(x)$ incident on an optical fiber, with $h(x)$ describing one particular optical mode. Eq. (27) then refers to the power P coupled into the mode and transported to a square law detector. In phase space, this overlap integral becomes

$$P = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} W_u(x, v) W_h(x, v) dx dv \quad (28)$$

where $W_u(x, v)$ and $W_h(x, v)$ are the normalized WDFs of the signal and the instrument, respectively.

The ideal generic detector may be modeled as a point detector, located at x_d , which receives optical power independent of the incident angle,

$$W_{pd}(x, v) = \delta(x - x_d) \quad (29)$$

The detected signal is the overlap integral,

$$P = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} W_u(x, v) W_{pd}(x, v) dx dv = \int_{-\infty}^{\infty} W_u(x_d, v) dv \quad (30)$$

which is consistent with the projection theorem of the WDF in Eq. (10). The signal power as a function of x is obtained with a continuum of point detectors.

This also means, the focal plane array of the lightfield camera effectively provides samples of a low pass filtered WDF only. It is possible, however, to add additional measurements with different instruments $W_h(x, v)$ and recover the signal WDF from the set of all measurements.

In particular, it is possible to envision power recordings obtained after passing the wavefront through a set of fractional Fourier transform systems. The fractional Fourier transformation generalizes the Fourier transforms in that it implements rotations of phase space at arbitrary angles. The rotation angle is proportional to the order of the fractional Fourier transformation.

Measuring power after fractional Fourier transforming the signal corresponds to the recording of projections of the WDF of the original signal along the rotation angle of the fractional Fourier transform. This means, a set of measurements covering all projection angles can be used for tomographic reconstruction of the WDF. Invoking the projections slice theorem of tomography identifies the projections at each angle as one slice of the AF of the signal. From knowledge of the AF the WDF and the signal can be estimated via an inverse Fourier transform.

Fractional Fourier transforms are not necessarily required to obtain the projections for tomographic reconstruction. For instance, Fresnel diffraction patterns may be recorded instead. Fig. 7 demonstrates, how projections along vertical lines $\overline{P_1 P_2}$ of the rotated WDF can be found after a horizontal shear, equivalent to free space propagation. While mapping recordings in Fresnel diffraction planes requires numerical scaling of the recording and presents inherent difficulties to obtain the equivalent of rotation angles close to 90° , it is typically easier to move the detector array along the optical axis, rather than implementing a large set of fraction Fourier transform systems.

This approach, known as phase-space tomography (Smithey *et al.*, 1993), is remarkable in that it provides a linear inverse algorithm for phase retrieval. This advantage is partially counterbalanced by the number of measurements required for the reconstruction of the WDF. For coherent wavefronts, a signal which is represented by N samples, is transformed into nominally $4N^2$ samples of the WDF, which includes the interference terms. Without additional prior knowledge, the linear retrieval then requires the same order of measurements to uniquely recover the WDF.

For partially coherent optical signals the number of samples to represent the phase-space distribution is equivalent to the number of sampling points to describe the mutual intensity. This means, in this case, phase-space tomography fully represents the complexity of the inverse problem.

For the recovery of two-dimensional images the projection slice theorem calls for anamorphic fractional Fourier transform systems, where the order of the fractional Fourier transform system can be changed independently for the two transverse coordinates. This means, a four-dimensional phase space has to be recovered to determine a two dimensional image. For coherent imaging, however, it is possible to reduce the experimental burden and recover the 2-D image as a set of 1-D slices.

The phase-space interpretation of tomographic signal recovery can be extended to other forms of phase-retrieval, most notably deterministic phase retrieval methods (Semichaevsky and Testorf, 2004) and pytochraphic imaging (Lubk and Röder, 2015). For coherent signals, it is possible to reduce the number of power measurements by surrendering the linearity of the reconstruction algorithm. For instance, deterministic phase retrieval from two closely located Fresnel diffraction planes are inherently based on the recovery the WDF from its local first order moments. This provides access to the AF and it first derivative along the frequency axis in turn providing magnitude and phase of the signal. The phase-space interpretation then provides a way to compare underlying principles of various phase retrieval methods.

Fig. 7 Equivalence of Fresnel diffraction and fractional Fourier transform. (a) Phase-space diagram of the signal. (b) Signal after fractional Fourier transform. The line $\overline{P_1 P_2}$ describes the projection associated with the signal detected in a fraction Fourier plane. (c) The phase-space after Fresnel diffraction. The horizontal shear can be selected to provide the same vertical projections as observed for the rotated phase-space distribution.

Fig. 8 Phase-space diagram of superresolution imaging: (a) The object bandwidth $\Delta\nu_o$ is twice the bandwidth supported by the optical system $\Delta\nu_{is}$. (b) Adapting the phase-space volume to the constraints of the imaging system allows transmission through the optical system without loss of information.

Superresolution Imaging

Superresolution imaging describes mathematical algorithms and imaging systems, which provide optical resolution superior to the nominal value associated with the size of the clear aperture of the system (Zalevsky and Mendlovic, 2004).

The mechanisms to achieve superresolution may be understood as a consequence of Shannon's information capacity theorem. Interpreting the imaging system as a continuous Gaussian channel of bandwidth $\Delta\nu_{is}$, field of view Δx_{is} and signal-to-noise ratio SNR , we expect to resolve

$$C = \Delta x_{is} \Delta \nu_{is} \log_2(1 + SNR) \quad (31)$$

bits of information from the image. If input signals to the system do not occupy the entire information capacity in terms of spatial support, or signal-to-noise ratio, it is possible to reassign information, which is encoded by the signal bandwidth, to either the signal extension or the SNR and transmit signals with a bandwidth exceeding the supported bandwidth of the system.

The phase-space interpretation is useful, in particular, to explore the trade-off between signal extension and bandwidth (Zalevsky et al., 2000). The generic operation of the this type of superresolution system is shown in Fig. 8. The input signal has bandwidth $\Delta\nu_o$ and a lateral extension Δx_o . The imaging systems only supports half the signal's bandwidth, i.e $\Delta\nu_{is} = \Delta\nu_o/2$, but the field of view Δx_{is} is twice the object extension. Then, a coding step can be implemented to transform the signal into the transmitted signal with half the original bandwidth, but twice the original signal extension. This type of bandwidth compression may be accomplished with quadratic phase systems which leave the phase-space volume in tact.

Fig. 9 Ambiguity function of the diffraction limited rectangular aperture: Cross-sections C correspond to the OTF in out-of-focus planes. The angle θ is related to the degree of defocus.

After passing the modified signal through the imaging system a decoding step is required to restore the original signal. Since the bandwidth of the transmitted signal, and consequently its resolution, is twice the nominal bandwidth of the system, this type of system effectively achieves superresolution imaging.

In order to recover a superresolved image of the object, the phase-space distribution at the output plane should not overlap with any other signal component.

Coding and decoding step may fundamentally differ depending on the imaging application. For instance, structured illumination sources may be used to move high frequencies of the object to the transmitted baseband, while numerical computation is used to assemble the image.

Pupil Design for Extended Depth of Field

The phase-space interpretation of wave aberrations can be combined with the concept of phase-space tomography to design imaging systems with increased depth of focus (see chapter 5 of [Testorf et al., 2009](#)). Conceptually, a defocus error can be described as the response of a linear system (Fresnel diffraction), which would suggest a removal of the defocus error by applying an inverse filter. However, the optical transfer function (OTF) for out-of-focus planes contains zeros, and the application of an inverse filter will typically result in images of low quality.

Alternatively, it is possible to design a lens function, for which the OTF never assumes the optimum shape of a diffraction limited imaging system, but which contains no zeros and a shape only depending weakly on the position of the object along the optical axis. This means, it is possible to apply an inverse filter numerically to the recorded low quality image to approximate more closely a diffraction limited OTF over a range of object planes superior to the depth of field predicted by the f-number of the lens. Originally, a cubic phase plate was suggested as a filter function to achieve this effect ([Dowski and Cathey, 1995](#)). Other families of filter functions were shown to provide a systems response suitable to extending the depth of field.

Recording defocused objects corresponds to the projections of the in-focus WDF after shearing relative to the x axis. This is equivalent to projections of the WDF at oblique angles (compare Section Phase-Space Tomography and Phase Retrieval). The Fourier transform of these projections are equivalent to slices of the in-focus AF at different angles. If the object is a perfect point source, the image represents the point-spread function of the system. The corresponding AF of the in-focus image, in [Fig. 9](#), displays the point-spread function along the $\bar{x}$ axis and the in-focus OTF along the $\bar{v}$ axis. Slices S represent the OTF at a plane which is out-of focus by a distance

$$\Delta z = \frac{\tan(\theta)}{\lambda} \quad (32)$$

For phase-space tomography each slice corresponds to information about the AF, which is used to reconstruct the signal. Here, the same concept can be used to evaluate pupil functions. The AF represents a simultaneous display of all out-of-focus OTFs for a particular object plane. A filter function suitable for extending the depth-of-field corresponds to an AF, with cross-sections not changing over the range of angles for which the defocus error will be removed.

Introduction

Information theory is an intuitively attractive mathematical approach for combining observation with communication, or sensing with processing. So far, however, this approach has remained largely in the realm of signal processing and transmission, as first formalized by Shannon and Wiener over 50 years ago. Recent extensions of this approach to imaging have mostly addressed the interpretation of images, without explicitly accounting for the critical limiting factors that constrain image gathering and restoration. Yet, to be useful in the characterization of imaging, information theory must account for these constraints and lead to a close correlation between predicted and actual performance. The characterization that is outlined here traces the rate of information from the scene to the observer; and it pairs this rate, first, with the theoretical minimum data rate to assess the efficiency with which information can be transmitted, and, second, with the maximum-realizable fidelity to assess the quality with which images can be restored. Further details, especially for the mathematical development of figures of merit and for the design of imaging systems, can be found in the Further Reading.

Model of Imaging

Description

Modern imaging systems usually have the following three stages, as depicted in Fig. 1:

1. *Image gathering*, to capture the radiance field that is either reflected or emitted by the scene and transform this field into a digital signal;
2. *Signal coding*, to encode the acquired signal for the efficient transmission and/or storage of data and decode the received signal for the restoration of images. The encoding may be either lossless (without loss of information) or lossy (with some loss of information), if a higher compression is required;
3. *Image restoration*, to produce a digital representation of the scene and transform this representation into a continuous image for the observer.

Human vision may be included in this model as a fourth stage, to characterize imaging systems in terms of the information rate that the eye of the observer conveys from the displayed image to the higher levels of the brain.

These stages are similar to each other in one respect: each contains one or more transfer functions, either continuous or discrete, followed by one or more sources of noise, also either continuous or discrete. The continuous transfer function of the image-gathering device (and of the human eye) is followed by sampling that transforms the captured radiance field into a discrete signal with analog magnitudes. In most devices the photodetection mechanism conveys this signal serially into an analog-to-digital (A/D) converter to produce a digital signal. However, analog signal processing in a parallel structure, akin to that in human vision, has many advantages that are increasingly emulated by neural networks.

This model of imaging differs from the classical model of communication that Shannon and Wiener addressed in two fundamental ways:

1. *The continuous-to-discrete transformation in image gathering.* Whereas communication is constrained critically only by bandwidth and noise, image gathering is constrained also by the compromise between blurring and aliasing, due to limitations in the response of optical apertures and in the sampling density of photodetection mechanisms. This additional constraint requires the rigorous treatment of insufficiently sampled signals throughout the imaging system.
2. *The sequence of image gathering followed by signal coding.* Whereas the characterization of communication addresses the perturbations that occur at the encoder and decoder or during transmission, the characterization of imaging systems must also address the perturbations in the image-gathering process prior to coding. These additional perturbations require a clear

Fig. 1 Model of digital imaging systems.

distinction between the information rate of the encoded signal and the associated theoretical minimum data rate or, more generally, between information and entropy.

The mathematical model of imaging that is outlined here accounts for the appropriate deterministic and stochastic (random) properties of natural scenes and for the critical limiting factors that constrain the performance of imaging systems. The corresponding formulations of the figures of merit are sufficiently general to account for a wide range of radiance field properties, photodetection mechanisms, and signal processing structures. However, the illustrations emphasize: (a) the salient properties of natural scenes that dominate the captured radiance field in the visible and near-infrared region under normal daylight conditions; and (b) the photodetector arrays that are used most frequently as the photodetection mechanism of image-gathering devices.

Radiance Field

The radiance field $L(x, y; \lambda)$, reflected by natural scenes, may be modeled approximately as

$$L(x, y; \lambda) = \frac{1}{\pi} I(\lambda) \rho(\lambda) \rho(x, y) \quad (1)$$

where $I(\lambda)$ and $\rho(\lambda)$, respectively, represent the spectral irradiance and reflectance properties as a function of the wavelength λ , and $\rho(x, y)$ represents the random reflectance properties as a function of the spatial coordinates (x, y) . Fig. 2 illustrates a model of $\rho(x, y)$ for which the power spectral density (PSD) $\hat{\Phi}_\rho(v, \omega)$ corresponds closely to that typical of natural scenes, as given by

$$\hat{\Phi}_\rho(v, \omega) = \frac{2\pi\mu_\rho^2\sigma_\rho^2}{[1 + (2\pi\mu_\rho\zeta)^2]^{3/2}} \quad (2)$$

where $\zeta^2 = v^2 + \omega^2$ and (v, ω) are the spatial frequency coordinates of the Fourier-transform domain (see Fig. 3). This model consists of random polygons, whose boundaries are distributed according to Poisson probability with a mean separation of μ_ρ , and whose magnitudes are distributed according to independent zero-mean Gaussian statistics of variance σ_ρ^2 . The constraints associated with Eq. (1) are satisfied by letting the mean reflectance $\bar{\rho} = 0.5$ and the standard deviation $\sigma_\rho \leq 0.2$.

Fig. 2 Model of reflectance $\rho(x, y)$.

Fig. 3 Normalized PSD of the reflectance $\rho(x, y)$.

Image Gathering

Fig. 4 depicts the basic optical geometry of an image-gathering device, in which the objective lens forms an image of the captured radiance field across the photodetector array, and the array transforms this image into a discrete signal. The sampling lattice (X, Y) , which determines the resolution of this device, is formed in angular units by the separation (X_p, Y_p) of the photodetector-array apertures and the distance ℓ_p as given for one of the dimensions by

$$X = 2 \tan^{-1} \frac{X_p}{2\ell_p} \approx \frac{X_p}{\ell_p} \text{ rad} = \frac{57.3 X_p}{\ell_p} \text{ deg} \quad (3)$$

Normally, the sampling lattice is square, as shown in Fig. 5, so that $X_p = Y_p$. Then the corresponding area of the photodetector apertures is $A_p = \gamma_p^2$, and the solid angle Ω of the instantaneous field of view (IFOV) is $\Omega \approx A_p / \ell_p^2$ ster.

The sampling lattice projected onto the scene at the distance ℓ_o has the dimensions $(X_o, Y_o) \approx (X\ell_o, Y\ell_o)$. Because these dimensions represent the finest spatial detail that normally can be restored, it is convenient to measure the mean spatial detail of the scene relative to the sampling lattice, as given by $\mu = \mu_p(X_o, Y_o)^{-1/2}$, which reduces to $\mu = \mu_p X_o^{-1}$ for $X = Y$. Hence, $\mu = 1$ indicates that the sampling interval is equal to the mean spatial detail.

The image-gathering process that transforms the continuous radiance field $L(x, y; \lambda)$ into the discrete signal $s(\mathbf{x}, \mathbf{y})$ may be modeled by the expression

$$s(\mathbf{x}, \mathbf{y}) = K \rho(\mathbf{x}, \mathbf{y}) * \tau(\mathbf{x}, \mathbf{y}) + n_p(\mathbf{x}, \mathbf{y}) \quad (4)$$

where the discrete coordinates $(\mathbf{x}, \mathbf{y}) = (mX, nY)$, and the symbol $*$ denotes continuous spatial convolution. This model accounts, in the simplest form, for the reflectance-to-signal conversion gain K , the reflectance $\rho(x, y)$ of the scene, the spatial response (SR) $\tau(x, y)$ of the image-gathering device, the continuous-to-discrete transformation by the photodetector-array lattice, and the discrete noise $n_p(\mathbf{x}, \mathbf{y})$ of the photodetectors. The discrete coordinates are defined by the sampling function

$$\mathbb{I} \equiv \mathbb{I}(\mathbf{x}, \mathbf{y}) = XY \sum_{\mathbf{x}, \mathbf{y}} \delta(\mathbf{x} - \mathbf{x}', \mathbf{y} - \mathbf{y}') \quad (5)$$

where $\delta(x, y)$ is the Dirac delta function; and the gain is given by

$$K = \frac{1}{\pi} A_\ell \Omega \int I(\lambda) \rho(\lambda) r(\lambda) d\lambda \quad (6)$$

where $A_\ell = \pi D^2/4$ is the area of the objective lens with diameter D , and $r(\lambda)$ is the responsivity of the photodetectors. This gain relates the magnitude of the signal $s(\mathbf{x}, \mathbf{y})$ directly to that of the reflectance $\rho(x, y)$; and, together with the variances σ_p^2 and σ_r^2 of the reflectance and the photodetector noise, respectively, it also determines the rms-signal-to-rms-noise ratio (SNR) $K\sigma_r/\sigma_p$.

The DFT of $s(\mathbf{x}, \mathbf{y})$ is the periodic spectrum $\tilde{s}(v, \omega)$ given by

$$\tilde{s}(v, \omega) = K \hat{\rho}(v, \omega) \hat{\tau}(v, \omega) * \mathbb{I} + \tilde{n}_p(v, \omega) \quad (7)$$

Fig. 4 Optical geometry of image-gathering device.

Fig. 5 Photodetector-array geometry and sampling passband.

where $\hat{\rho}(v, \omega)$ is the spectrum of the reflectance, $\hat{\tau}(v, \omega)$ is the spatial frequency response (SFR) of the image-gathering device, and $\hat{n}_p(v, \omega)$ is the spectrum of the photodetector noise. The symbol $\hat{\mathbb{I}}$ is the Fourier transform of the sampling function $\mathbb{I}$. It accounts for the sidebands generated by the sampling process and is given by

$$\hat{\mathbb{I}} \equiv \hat{\mathbb{I}}(v, \omega) = \sum_{v, \omega} \delta(v - v, \omega - \omega) \quad (8)$$

where $(v, \omega) = (m/X, n/Y)$. The corresponding sampling passband is

$$\hat{B} = \left\{ (v, \omega); |v| < \frac{1}{2X}, |\omega| < \frac{1}{2Y} \right\} \quad (9)$$

The above expression for $\hat{s}(v, \omega)$ can be rewritten more conveniently as

$$\hat{s}(v, \omega) = K\hat{\rho}(v, \omega)\hat{\tau}(v, \omega) + \hat{n}(v, \omega) \quad (10)$$

where

$$\hat{n}(v, \omega) = \hat{n}_a(v, \omega) + \hat{n}_p(v, \omega) \quad (11)$$

is the spectrum of the total noise in the acquired signal. The first term $\hat{n}_a(v, \omega)$ represents the aliased signal components caused by insufficient sampling, as given by

$$\hat{n}_a(v, \omega) = K\hat{\rho}(v, \omega)\hat{\tau}(v, \omega) * \hat{\mathbb{I}}_s \quad (12)$$

where

$$\hat{\mathbb{I}}_s \equiv \hat{\mathbb{I}}_s(v, \omega) = \sum_{v, \omega \neq (0,0)} \delta(v - v, \omega - \omega) \quad (13)$$

If, for spatial coordinates at either the scene or the photodetector array, the unit of (x, y) is meters, then the unit of (v, ω) is cycles m^{-1} ; and if, for angular coordinates centered at the objective lens, the unit of (x, y) is radians, then the unit of (v, ω) is cycles rad^{-1} . Either way, it is convenient to normalize the sampling intervals to unity (i.e., $X=Y=1$). Then the area of the sampling passband is $|\hat{B}| = 1$, the unit of (x, y) is samples, and the unit of (v, ω) is cycles $sample^{-1}$.

The SFR $\hat{\tau}(v, \omega)$ of the image-gathering device is

$$\hat{\tau}(v, \omega) = \hat{\tau}_e(v, \omega)\hat{\tau}_p(v, \omega) \quad (14)$$

where $\hat{\tau}_e(v, \omega)$ and $\hat{\tau}_p(v, \omega)$ are the SFRs of the objective lens and photodetector apertures, respectively. This SFR may be modeled approximately by the circularly symmetric Gaussian shape

$$\hat{\tau}(v, \omega) = \exp[-(\zeta/\zeta_c)^2] \quad (15)$$

where, as shown in Fig. 6, the optical-response index ζ_c controls the trade-off between the blurring that is caused by the decrease of the SFR inside the sampling passband and the aliasing that is caused by the extension of the SFR beyond this passband.

Signal Coding

Signal coding may be divided into two stages, as depicted in Fig. 1. The first stage, which is represented by the digital operator $\tau_c(x, y)$ and the quantization noise $n_q(x, y; \kappa)$, accounts for manipulations of the acquired signal that seek to extract those features of the captured radiance field considered to be perceptually most significant, which usually entails some loss of information. The second stage, which is represented by the encoder, accounts for manipulations that seek to reduce redundancies in the acquired

Fig. 6 SFRs $\hat{\tau}(v, \omega)$ of the image-gathering device relative to the sampling passband $\hat{B}$ for unit sampling intervals (i.e., $X=Y=1$).

signal, without loss of information. The resultant encoded signal $s_e(\mathbf{x}, \mathbf{y}; \boldsymbol{\kappa})$ may be expressed in the same form as Eq. (4) for the acquired signal $s(\mathbf{x}, \mathbf{y})$ as

$$s_e(\mathbf{x}, \mathbf{y}; \boldsymbol{\kappa}) = s(\mathbf{x}, \mathbf{y}) \otimes \tau_e(\mathbf{x}, \mathbf{y}) + n_q(\mathbf{x}, \mathbf{y}; \boldsymbol{\kappa}) \quad (16)$$

where the symbol $\otimes$, denotes discrete spatial convolution, and $n_q(\mathbf{x}, \mathbf{y}; \boldsymbol{\kappa})$ is the quantization noise. If the data transmission and/or storage are error-free, as is assumed here, then the signal that leaves the decoder remains identical to the signal that enters the encoder.

The DFT of $s_e(\mathbf{x}, \mathbf{y}; \boldsymbol{\kappa})$ is the periodic spectrum $\tilde{s}_e(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa})$ given in the same form as Eq. (10) by

$$\tilde{s}_e(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) = K \hat{\rho}(\mathbf{v}, \boldsymbol{\omega}) \hat{\Gamma}_e(\mathbf{v}, \boldsymbol{\omega}) + \hat{n}_e(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) \quad (17)$$

where

$$\hat{\Gamma}_e(\mathbf{v}, \boldsymbol{\omega}) = \hat{\tau}(\mathbf{v}, \boldsymbol{\omega}) \hat{\tau}_e(\mathbf{v}, \boldsymbol{\omega}) \quad (18)$$

is the throughput SFR from image gathering to transmission, and

$$\hat{n}_e(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) = \hat{n}(\mathbf{v}, \boldsymbol{\omega}) \hat{\tau}_e(\mathbf{v}, \boldsymbol{\omega}) + \tilde{n}_q(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) \quad (19)$$

is the accumulated noise in the encoded signal. For $\log \boldsymbol{\kappa}$ -bit quantization, where $\log \boldsymbol{\kappa}$ is the number of uniformly spaced quantization levels, $\tilde{n}_q(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa})$ may be treated (for ≥ 4) as independent Gaussian noise with the PSD

$$\tilde{\Phi}_q(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) = \sigma_q^2 = (\sigma_{s_e}/\boldsymbol{\kappa})^2 \quad (20)$$

where $\sigma_{s_e}^2$ is the variance given approximately by

$$\sigma_{s_e}^2 \approx K^2 \int_B \int \hat{\Phi}_\rho(\mathbf{v}, \boldsymbol{\omega}) |\hat{\Gamma}_e(\mathbf{v}, \boldsymbol{\omega})|^2 d\mathbf{v} d\boldsymbol{\omega} \quad (21)$$

Image Restoration

Image restoration, as depicted in Fig. 1, transforms the decoded signal $s_e(\mathbf{x}, \mathbf{y}; \boldsymbol{\kappa})$ into the digital image $r(\bar{\mathbf{x}}, \bar{\mathbf{y}}; \boldsymbol{\kappa})$ as modeled by the expression

$$r(\bar{\mathbf{x}}, \bar{\mathbf{y}}; \boldsymbol{\kappa}) = \overline{\overline{\overline{s_e}}}(\mathbf{x}, \mathbf{y}; \boldsymbol{\kappa}) \otimes \Psi(\bar{\mathbf{x}}, \bar{\mathbf{y}}; \boldsymbol{\kappa}) \quad (22)$$

The operation indicated by $\overline{\overline{\overline{s_e}}}(\mathbf{x}, \mathbf{y}; \boldsymbol{\kappa})$ (called zero padding) prepares the decoded signal for image restoration with interpolation, and the operator $\Psi(\bar{\mathbf{x}}, \bar{\mathbf{y}}; \boldsymbol{\kappa})$ produces the digital image $r(\bar{\mathbf{x}}, \bar{\mathbf{y}}; \boldsymbol{\kappa})$ on the interpolation lattice $\overline{\overline{\overline{\cdot}}}$ that is Z times denser than the sampling lattice $\overline{\overline{\cdot}}$. If the interpolation in the image restoration is sufficiently dense (normally, for $Z \geq 4$), then the blurring and raster effects of the image-display process are suppressed entirely. This condition leads not only to the best realizable image quality but also to the simplest expression for the continuous displayed image, as given in the same form as Eqs. (10) and (17) by

$$\hat{R}(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) = \hat{\rho}(\mathbf{v}, \boldsymbol{\omega}) \hat{\Gamma}_r(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) + \hat{n}_r(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) \quad (23)$$

where

$$\hat{\Gamma}_r(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) = \hat{\tau}(\mathbf{v}, \boldsymbol{\omega}) \hat{\tau}_e(\mathbf{v}, \boldsymbol{\omega}) \hat{\Psi}(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) \quad (24)$$

is the throughput SFR from image gathering to display, and

$$\hat{n}_r(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) = K^{-1} \hat{n}_e(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) \hat{\Psi}(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) = \hat{n}_{ar}(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) + \hat{n}_{pr}(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) + \hat{n}_{qr}(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) \quad (25)$$

is the accumulated noise in the restored image. This noise may be expressed explicitly by substituting the noise components given above. The noise due to the granularity in image-display mediums is not accounted for here.

The Wiener filter, that minimizes the mean-square error due to the perturbations in image gathering and coding, is given by

$$\hat{\Psi}(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) = \frac{\hat{\Phi}'_\rho(\mathbf{v}, \boldsymbol{\omega}) \hat{\Gamma}_e^*(\mathbf{v}, \boldsymbol{\omega})}{\hat{\Phi}'_\rho(\mathbf{v}, \boldsymbol{\omega}) |\hat{\Gamma}_e(\mathbf{v}, \boldsymbol{\omega})|^2 + \hat{\Phi}'_{n_e}(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa})} \quad (26)$$

where $\hat{\Phi}'(\mathbf{v}, \boldsymbol{\omega}) = \sigma_\rho^{-2} \hat{\Phi}_\rho(\mathbf{v}, \boldsymbol{\omega})$ is the normalized PSD of the radiance field and

$$\hat{\Phi}'_{n_e}(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) = (K\sigma_\rho)^{-2} [\hat{\Phi}_n(\mathbf{v}, \boldsymbol{\omega}) |\tilde{\tau}_e(\mathbf{v}, \boldsymbol{\omega})|^2 + \tilde{\Phi}_q(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa})]$$

is the normalized PSD of the accumulated noise in the encoded signal. If the photodetector noise is white so that the PSD $\tilde{\Phi}_p(\mathbf{v}, \boldsymbol{\omega})$ is equal to its variance σ_p^2 and the PSD $\tilde{\Phi}_q(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa})$ is equal to its variance σ_q^2 , then the PSD of the noise simplifies to

$$\hat{\Phi}'_{n_e}(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) = \hat{\Phi}'_{n_e}(\mathbf{v}, \boldsymbol{\omega}) + \hat{\Phi}'_q(\mathbf{v}, \boldsymbol{\omega}; \boldsymbol{\kappa}) \quad (27)$$

where

$$\hat{\Phi}'_{n_e}(\mathbf{v}, \boldsymbol{\omega}) = [\hat{\Phi}'_\rho(\mathbf{v}, \boldsymbol{\omega}) \hat{\tau}(\mathbf{v}, \boldsymbol{\omega})]^2 * \overline{\overline{\overline{\delta}}} + (K\sigma_\rho/\sigma_\rho)^{-2} |\hat{\tau}_e(\mathbf{v}, \boldsymbol{\omega})|^2 \quad (28)$$

and

$$\hat{\Phi}'_q(v, \omega; \kappa) = (K\sigma_\rho/\sigma_{s_e})^{-2}\kappa^{-2} \quad (29)$$

These simplifying conditions permit the Wiener filter given above and the figures of merit given below to be expressed as a function of the SNR $K\sigma_\rho/\sigma_{s_e}$, which can be specified without accounting explicitly for either the gain K or the variances σ_ρ^2 and $\sigma_{s_e}^2$.

Figures of Merit

Information Rate $\mathcal{H}$

The information rate $\mathcal{H}$ (in bits sample⁻¹) of the encoded signal $s_e(\mathbf{x}, \mathbf{y}; \kappa)$ is defined by

$$\mathcal{H} = \mathcal{E}[\tilde{s}_e(v, \omega; \kappa)] - \mathcal{E}[\tilde{s}_e(v, \omega; \kappa) | \hat{\rho}(v, \omega) : (v, \omega) \in \hat{B}] \quad (30)$$

where the first term, $\mathcal{E}[\cdot]$ represents the entropy of $\tilde{s}_e(v, \omega; \kappa)$ and the second term, $\mathcal{E}[\cdot | \cdot]$ represents the conditional entropy of this signal when the reflectance spectrum $\hat{\rho}(v, \omega)$ within the sampling passband $\hat{B}$ is known. For the assumptions that have been made about image gathering and coding, the conditional entropy becomes the entropy of the accumulated noise $\hat{n}_e(v, \omega; \kappa)$, so that $\mathcal{H}$ simplifies to

$$\mathcal{H} = \mathcal{E}[\tilde{s}_e(v, \omega; \kappa)] - \mathcal{E}[\hat{n}_e(v, \omega; \kappa) : (v, \omega) \in \hat{B}] = \frac{1}{2} \int_{\hat{B}} \int \log \left[1 + \frac{\hat{\Phi}'_\rho(v, \omega) |\hat{\Gamma}_e(v, \omega)|^2}{\hat{\Phi}'_{n_e}(v, \omega; \kappa)} \right] dv d\omega \quad (31)$$

The theoretical upper bound of $\mathcal{H}$ is Shannon's channel capacity $\mathcal{C}$ for a bandwidth-limited system, with white photodetector noise and an average power limitation (here the variance σ_ρ^2), as given by

$$\mathcal{C} = \frac{1}{2} \log[1 + (K\sigma_\rho/\sigma_\rho)^2] \quad (32)$$

$\mathcal{H}$ can reach $\mathcal{C}$ only when

$$\begin{aligned} \hat{\Phi}_\rho(v, \omega) &= \begin{cases} \sigma_\rho^2, & (v, \omega) \in \hat{B} \\ 0, & \text{elsewhere} \end{cases} \\ \hat{\tau}(v, \omega) &= \begin{cases} 1, & (v, \omega) \in \hat{B} \\ 0, & \text{elsewhere} \end{cases} \end{aligned} \quad (33)$$

However, neither of these two conditions can occur in practice because both the PSD $\hat{\Phi}_\rho(v, \omega)$ of natural scenes and the SFR $\hat{\tau}(v, \omega)$ of image-gathering devices decrease gradually with increasing spatial frequency, as depicted in Figs. 3 and 6, respectively. Hence, $\mathcal{H}$ can never reach $\mathcal{C}$.

Theoretical Minimum Data Rate $\mathcal{E}$

The theoretical minimum data rate $\mathcal{E}$ (also in bits sample⁻¹) that is required to convey the information rate $\mathcal{H}$ is defined by

$$\mathcal{E} = \mathcal{E}[\tilde{s}_e(v, \omega; \kappa)] - \mathcal{E}[\tilde{s}_e(v, \omega; \kappa) | \tilde{s}(v, \omega)] \quad (34)$$

where the second term, $\mathcal{E}[\cdot | \cdot]$ is the uncertainty of $\tilde{s}_e(v, \omega; \kappa)$ when $\tilde{s}(v, \omega)$ is known. For the assumptions that have been made about the coding process, the conditional entropy becomes the entropy $\mathcal{E}[\hat{n}_q(v, \omega; \kappa)]$ of the quantization noise, so that $\mathcal{E}$ simplifies to

$$\mathcal{E} = \mathcal{E}[\tilde{s}_e(v, \omega; \kappa)] - \mathcal{E}[\hat{n}_q(v, \omega; \kappa)] = \frac{1}{2} \int_{\hat{B}} \int \log \left[1 + \frac{\hat{\Phi}'_\rho(v, \omega) |\hat{\Gamma}_e(v, \omega)|^2 + \hat{\Phi}'_{n_e}(v, \omega)}{\hat{\Phi}'_q(v, \omega; \kappa)} \right] dv d\omega \quad (35)$$

This expression for $\mathcal{E}$ represents the entropy of completely decorrelated data.

Information Efficiency $\mathcal{H}/\mathcal{E}$

The information efficiency of completely decorrelated data is defined by the ratio $\mathcal{H}/\mathcal{E}$. This ratio reaches its upper bound $\mathcal{H}/\mathcal{E} = 1$ when $\hat{\Phi}'_{n_e}(v, \omega) \ll \hat{\Phi}'_\rho(v, \omega) |\hat{\Gamma}_e(v, \omega)|^2$ and $\hat{\Phi}'_{n_e}(v, \omega) \ll \hat{\Phi}'_\rho(v, \omega; \kappa)$ because then both Eq. (31) for $\mathcal{H}$ and Eq. (35) for $\mathcal{E}$ reduce to the same expression

$$\mathcal{H} = \mathcal{E} = \frac{1}{2} \int_{\hat{B}} \int \log \left[1 + \frac{\hat{\Phi}'_\rho(v, \omega) |\hat{\Gamma}_e(v, \omega)|^2}{\hat{\Phi}'_q(v, \omega; \kappa)} \right] dv d\omega \quad (36)$$

This upper bound can be approached with a small loss in $\mathcal{H}$ only when the aliasing and photodetector noise are small. Hence, the electro-optical design that optimizes $\mathcal{H}$ also optimizes $\mathcal{H}/\mathcal{E}$. However, a compromise always remains between $\mathcal{H}$ and $\mathcal{H}/\mathcal{E}$ in the selection of the number of quantization levels: $\mathcal{H}$ favors fine quantization, whereas $\mathcal{H}/\mathcal{E}$ favors coarse quantization.

Maximum-Realizable Fidelity $\mathcal{F}$

The maximum-realizable fidelity $\mathcal{F}$ of the images restored with the Wiener filter $\hat{\Psi}(v, \omega; \kappa)$ can be expressed as a function of the throughput SFR $\hat{\Gamma}_r(v, \omega; \kappa)$ given by Eq. (24) as

$$\mathcal{F} = \int \int \hat{\Phi}'_\rho(v, \omega) \hat{\Gamma}_r(v, \omega; \kappa) dv d\omega \quad (37)$$

or, equivalently, as a function of the integrand $\hat{\mathcal{H}}(v, \omega; \kappa)$ of the information rate $\mathcal{H}$ given by Eq. (31) as

$$\mathcal{F} = \int \int \hat{\Phi}'_\rho(v, \omega) [1 - 2^{-\hat{\mathcal{H}}(v, \omega; \kappa)}] dv d\omega \quad (38)$$

This relationship between fidelity and information rate can be extended to other goals. For example, the enhancement of spatial features (e.g., edges and boundaries), for robotic vision, can be accommodated by letting $\tilde{\tau}_c(v, \omega)$ be the desired feature-enhancement filter.

Performance and Design Trade-offs

Electro-optical Design

Fig. 7 presents the information rate $\mathcal{H}$ (for lossless encoding) as a function of the optical-response index ζ_c and the mean spatial detail μ . The information rate $\mathcal{H}$ versus ζ_c is given for several SNRs $K\sigma_p/\sigma_p$ and $\mu=1$, and $\mathcal{H}$ versus μ is given for the three informationally optimized designs specified in Table 1.

The curves show that $\mathcal{H}$ can reach its highest possible value only when both of the following conditions are met:

1. The relationship between the SFR $\hat{\tau}(v, \omega)$ and the sampling passband $\hat{B}$ is chosen to optimize $\mathcal{H}$ for the available SNR $K\sigma_p/\sigma_p$. This design is said to be informationally optimized.

Fig. 7 Information rate $\mathcal{H}$ versus the optical-response index ζ_c and the mean spatial detail μ (relative to the sampling interval). The designs are specified in Table 1, and the SFRs $\hat{\tau}(v, \omega)$ for ζ_c are shown in Fig. 6.

Table 1 Informationally optimized designs

Design	$K\sigma_p/\sigma_p$	ζ_c	$\mathcal{H}^*$
1	256	0.3	4.4
2	64	0.4	3.3
3	16	0.5	2.2

* $\mu=1$.

2. The relationship between the sampling passband $\hat{B}$ and the PSD $\hat{\Phi}_p(v, \omega)$ is chosen to optimize $\mathcal{H}$. For the PSDs $\hat{\Phi}_p(v, \omega)$ typical of natural scenes, the best match occurs when the sampling interval is near the mean spatial detail of the scene (i.e., when $\mu \approx 1$).

These conditions are consistent with those for which the information rate $\mathcal{H}$ reaches Shannon's channel capacity $\mathcal{C}$. However, blurring and aliasing constrain $\mathcal{H}$ to values that are smaller than $\mathcal{C}$ by a factor of nearly two (i.e., $\mathcal{H}\mathcal{C}/2$). Hence, these conditions replace the role of white and band-limited signals in classical communication theory, to establish an upper bound on the information rate in imaging systems.

The above two conditions appeal intuitively when the problem of image restoration is considered:

1. The result that the SFR $\hat{\tau}(v, \omega)$ that optimizes $\mathcal{H}$ depends on the available SNR is consistent with the observation that, in one extreme, when the SNR is low, substantial blurring should be avoided because the photodetector noise would constrain the enhancement of fine spatial detail even if aliasing were negligible. In the other extreme, when the SNR is high, substantial aliasing should be avoided so that this enhancement is relieved from any constraints except those that the sampling passband inevitably imposes.
2. The result that $\mathcal{H}$ reaches its highest value when the sampling interval is near the mean spatial detail of the scene is consistent with the observation that, ordinarily, it would not be possible to restore spatial detail that is finer than the sampling interval, whereas it would be possible to restore much coarser detail from fewer samples.

Information Rate and Data Rate

Fig. 8 presents an information-entropy $\mathcal{H}(\mathcal{E})$ plot that characterizes the relationship between the information rate $\mathcal{H}$ of the encoded signal and the associated theoretical minimum data rate, or entropy, $\mathcal{E}$ for η -bit quantization. The encoder SFR $\hat{\tau}_e(v, \omega)$ is assumed to be unity. The plot illustrates the trade-off between $\mathcal{H}$ and $\mathcal{E}$ in the selection of the number of quantization levels for encoding the acquired signal. It shows, in particular, that the design that realizes the highest information rate $\mathcal{H}$ also enables the encoder to realize the highest information efficiency $\mathcal{H}/\mathcal{E}$. This result appeals intuitively, because the perturbations due to aliasing and photodetector noise that interfere with the image restoration can also be expected to do so with the signal decorrelation.

Throughput SFR

Fig. 9 illustrates the SFRs $\hat{\tau}(v, \omega)$ and $\hat{\Psi}(v, \omega; \kappa)$ of the image-gathering device and Wiener filter, respectively, and of their product, the throughput SFR $\hat{\Gamma}_r(v, \omega; \kappa)$ for the three designs specified in **Table 1**. As the accumulated noise becomes negligible, $\hat{\Gamma}_r(v, \omega; \kappa)$ approaches the ideal SFR of the classical communication channel, which is unity inside the sampling passband and zero outside.

Information Rate, Fidelity and Robustness

The PSD $\hat{\Phi}_p(v, \omega)$ of a scene is seldom known when images are restored. Moreover, even if the PSD were known to be the one given by **Eq. (2)**, then the mean spatial detail μ would usually remain uncertain because it depends, not only on the properties of the scene, but also on the angular resolution and viewing distance of the image-gathering device. In practice, therefore, image restorations have to rely on estimates of the statistical properties of scenes. The tolerance of the quality of the restored image to errors in these estimates is referred to as the robustness of the image restoration.

Fig. 10 presents the information rate $\mathcal{H}$ and the corresponding maximum-realizable fidelity $\mathcal{F}$ for matched and mismatched Wiener restorations. These restorations represent the digital image $R(\bar{x}, \bar{y}; \kappa)$ or, equivalently, the continuous image $R(x, y; \kappa)$ displayed on a noise-free medium. The matched restorations use the correct value of μ , whereas the mismatched restorations use wrong estimates of μ . These curves reveal that the informationally optimized designs produce the highest fidelity and robustness, and that both improve with increasing $\mathcal{H}$. Moreover, these curves reveal that, ordinarily, one cannot go far wrong in Wiener restorations by assuming that the mean spatial detail is equal to the sampling interval (i.e., $\mu = 1$). This observation appeals

Fig. 8 The information-entropy $\mathcal{H}(\mathcal{E})$ plot of the information rate $\mathcal{H}$ versus the associated theoretical minimum data rate $\mathcal{E}$ for η -bit quantization. The designs are specified in **Table 1**.

Fig. 9 SFRs of image gathering, restoration, and throughput. The designs are specified in Table 1.

Fig. 10 Information rate $\mathcal{H}$ and maximum-realizable fidelity $\mathcal{F}$ versus the optical-response index ζ_c for two SNRs $K\sigma_\rho/\sigma_p$. $\mathcal{F}$ is given for the matched ($\langle\mu\rangle=1$) and two mismatched Wiener restorations.

intuitively because spatial detail that is much smaller cannot be resolved, and detail that is larger is not degraded substantially by blurring and aliasing.

Information Rate and Visual Quality

Figs. 11 and 12 present Wiener restorations and their three components, as given by Eq. (23), where $\rho(x, y) * \Gamma_r(x, y; \kappa)$ accounts for blurring, $n_{ar}(x, y; \kappa)$ accounts for aliasing, and $n_{pr}(x, y; \kappa)$ accounts for photodetector noise. The contrast of the illustrations of the

Fig. 11 Images restored with the Wiener filter and their three components for designs 1 (top) and 3 (bottom).

Fig. 12 Images restored with the Wiener filter and their three components for designs 1 (top) and 3 (bottom).

two noise components has been increased by a factor of four to improve their visibility. The extraneous structure that aliasing produces in the images of the resolution wedges is commonly referred to as Moiré pattern. The corresponding distortion in the images of the random polygons emerges more subtly as jagged (or staircase) edges.

The images are formed from a set of 64×64 samples with a $Z=4$ interpolation and have a 4×4 cm format. If these images were displayed in a smaller format, then the jagged edges could not be resolved by the observer and would appear to be the result of blurring or photodetector noise instead of aliasing. Aliasing has, therefore, often been overlooked as a significant source of image degradation.

The Wiener restoration produces images in which fine spatial detail near the limit of resolution normally has a high contrast approaching that in the scene. However, these images also tend to contain visually annoying defects, due to the accumulated noise

Fig. 13 Images restored with the Wiener filter and enhanced for visual quality. The large, medium, and small formats contain 16, 32 and 64 pixels/cm, respectively.

and the ringing near sharp edges (Gibbs phenomenon). Hence, it is often desirable to combine this restoration with an enhancement filter that gives the user some control over the trade-off among fidelity, sharpness and clarity.

Fig. 13 presents images for which the Wiener restorations given in **Figs. 11** and **12** are enhanced for visual quality by suppressing some of the defects due to aliasing and ringing. This enhancement improves clarity at the cost of a small loss in sharpness. The images are produced again from 64×64 pixels, but they are displayed in three different formats. The smallest format, with a density of 64 pixels/cm, corresponds to a display of 256×256 pixels in a 4×4 cm area, which is typical of the images found in the prevalent digital image-processing literature. As can be observed, this small format leads to images that are indistinguishable from each other because they hide many of the distortions that larger formats clearly reveal.

In general, if the images are displayed in a format that is large enough to reveal the finest spatial detail near the limit of resolution of the imaging system, then distortions due to the perturbations in this system become also visible. When no effort is spared to reduce these distortions without a perceptual loss of resolution and sharpness, then it becomes strongly evident that the best visual quality with which images can be restored improves with increasing information rate, even after the fidelity has essentially reached its upper bound. This improvement continues until it is gradually ended by the unavoidable compromise among sharpness, aliasing, and ringing as well as by the granularity of the image display.

Concluding Remarks

The performance of image-gathering devices and the human eye is constrained by the same critical limiting factors. When these factors are accounted for properly, then it emerges that the design of the image-gathering device that is optimized for the highest realizable information rate corresponds closely, under appropriate conditions, to the design of the human eye that evolution has

optimized for viewing the real world. This convergence of information theory and evolution toward the same design clearly supports the extension of information theory to the characterization of imaging systems.

Numerous other information-theoretic characterizations of imaging are now emerging. However, none of these characterizations accounts for the critical limiting factors that constrain image gathering and restoration, as outlined here. Hence, it is not possible for them to address the efficiency and accuracy with which images can be conveyed. Moreover, none of these characterizations combines observation with communication, or sensing with processing, in a general formalization. Instead, each of them still deals with a particular measurement or imaging problem. Hence, the role of information theory in imaging is far from mature. Many challenges remain: to develop general formalizations, to account for physical phenomena, and to correlate predictions with measurements.

Introduction

A digital image is an array (2D image) or a cube (3D image) of quantized numbers, providing a representation of a physical object or a map of some distributed property of the object (density of matter, energy, etc.). It can be obtained by digitizing the original image (for instance, a photograph) or can be directly formed by the outputs of the imaging system (digital camera, microscope, telescope, etc.). When visualized on a suitable image display device, a digital image must provide a representation of the physical object which can be easily interpreted and analyzed. In many cases, however, this condition is not satisfied. We give two typical examples.

The first is that of an image degraded by blurring which can be introduced by defects of the optical systems (such as aberrations) or by image motion, image defocusing, etc. The representation of the object does not have the quality which should be desirable for its interpretation.

The second case is even more important and arises when the output of the imaging system is not directly related to the physical quantity to be imaged. For instance, in X-ray tomography, the output of a detector is the attenuation of an X-ray pencil crossing the body while the quantity to be imaged is the density of the body.

In the situations described above, the desired image can be obtained by solving a number of mathematical problems. If we denote f as the object, namely the target of the imaging system, and g as the image of f provided by the system, then the problems to be solved can be summarized as follows:

- develop a physical model of the system to obtain a mathematical relationship between the object f and the image g ; the computation of g from a given f is usually called the solution of the direct problem;
- solve the problem of obtaining the physical quantity f from given outputs g of the system; this second step is usually called the solution of the inverse problem.

The digital image of f , obtained by solving an inverse problem, is a computed one, generated by the computer where the algorithm for the solution of the inverse problem has been implemented.

It may be convenient to formulate both the direct and the inverse problem in terms of functions rather than arrays, cubes, etc., because such a formulation allows the use of powerful tools of functional analysis for their investigation. Next, the results obtained in the continuous case can be used for understanding the features of the corresponding discrete problem. In most important applications, for instance, the relationship between f and g is linear so that, in the discrete version of the direct problem, one obtains g by applying a suitable matrix A to f while, in the discrete version of the inverse problem, one obtains f from g by solving a linear algebraic system. However, the solution of the inverse problem is not so simple and the difficulties can be understood by looking at the corresponding continuous problem.

The basic reason relies on the fact that inverse problems are ill-posed in the sense of Hadamard: the solution may not exist; even if it exists it may not be unique; and, even if it exists and is unique, it may not depend continuously on the data. The last statement means that a small perturbation of the data, such as that caused by noise or any kind of experimental error, can completely modify the solution.

Inverse problems are ill-posed because imaging systems do not transmit complete information about the physical object. Therefore, the problem is to extract the useful information contained in the data or, in mathematical terms, to look for approximate solutions which are stable against noise. This is the purpose of a mathematical theory introduced in its general form by the Russian mathematician, Tikhonov and known as regularization theory.

We illustrate the general framework outlined above by means of a specific example – image deconvolution, also known as image deblurring, image restoration, etc. The object f is the image which should be recorded in the absence of degradation, while g is the image corrupted by aberrations or other causes of blurring. Both f and g are functions of 2D (or 3D) space variables $\mathbf{x}$ which are the coordinates of a point in the image domain. If the imaging system is isoplanatic, then it is described by a space-invariant point spread function (PSF) $K(\mathbf{x})$, which is the image of a point source located in the center of the image domain. The PSF provides the response of the system to any point source wherever it is located. On the other hand, its Fourier transform, the transfer function $\hat{K}(\omega)$ (the hat denotes Fourier transform and ω , the spatial frequencies associated to the space variables $\mathbf{x}$), tells us how a signal of a fixed frequency is propagated through the linear system, so that the blurring can also be viewed as a sort of frequency filtering.

Under these assumptions the image g is the convolution product of object f and PSF K :

$$g(\mathbf{x}) = \int K(\mathbf{x} - \mathbf{x}')f(\mathbf{x}')d\mathbf{x}' \quad (1)$$

and the solution of the direct problem is just the computation of a convolution product.

The image g , as given by Eq. (1), is the so-called noise-free image. The actually recorded image g_r is affected by a noise term and, in general, it can be written in the following form:

$$g_r(\mathbf{x}) = g(\mathbf{x}) + n(\mathbf{x}) \quad (2)$$

where $n(\mathbf{x})$ is a function describing noise contamination. It is a random function and, therefore, it is unknown even if one understands its statistical properties. We point out that Eq. (2) does not imply that the noise is additive or signal independent. For instance, in microscopy and astronomy, the contamination of the image is due both to photon noise, which satisfies Poisson statistics, and read-out noise, which is basically Gaussian and white. Therefore the noise term in Eq. (2) must only be intended as the difference between the noisy and the noise-free image.

In a first attempt at approaching the inverse problem, it seems quite natural to ignore the noise term $n(\mathbf{x})$ and to solve Eq. (1) for $f(\mathbf{x})$ with $g(\mathbf{x})$ replaced by $g_r(\mathbf{x})$. Then, by taking the Fourier transform of both sides of this equation and using the well-known convolution theorem, one finds the following relationship:

$$\hat{g}_r(\omega) = \hat{K}(\omega)\hat{f}(\omega) \quad (3)$$

which relates the Fourier transform of f and g to the transfer function of the imaging system.

The solution of this equation looks elementary. However, a first problem is due to the fact that an optical system is generally band-limited; its band Ω is the bounded domain of spatial frequencies where the transfer function is different from zero. Since the noise is not band-limited or, at least, has a band much broader than that of the optical system, outside Ω the right-hand side of Eq. (3) is zero while the left-hand side is not; in other words, the solution of the deconvolution problem, as formulated above, does not exist because no object f satisfies Eq. (3) everywhere. In this particular case, one can circumvent the problem by applying a suitable filter to $g_r(\mathbf{x})$ in order to suppress the out-of-band noise.

The second problem is the nonuniqueness of the solution of the problem with the filtered data. This is due to the so-called invisible objects, namely objects whose Fourier transform is zero on Ω , so that the corresponding images are exactly zero. If we find a solution of the deconvolution problem, by adding an arbitrary invisible object to this solution, we find another solution of the same problem. A well-defined solution can be obtained by requiring its Fourier transform to be zero outside Ω . In other words, we set to zero what is not transmitted by the imaging system.

The standard way for approaching the previous questions is to look for solutions in the least-squares sense, namely for objects which minimize the functional:

$$\varepsilon^2(f) = \|K * f - g_r\|^2 \quad (4)$$

where $*$ denotes the convolution product, as defined in Eq. (1), and the right-hand side is the square of the L^2 -norm (which can also be interpreted as energy) of the discrepancy between the recorded image g_r and the computed image $K * f$. If one looks for a least-squares solution with minimal energy then one automatically re-obtains the solution discussed above, namely an object whose Fourier transform in Ω is given by

$$\hat{f}_{\text{inv}}(\omega) = \frac{\hat{g}_r(\omega)}{\hat{K}(\omega)} \quad (5)$$

and is zero outside Ω . Such a solution is that provided by the so-called inverse filter.

However, there is an additional difficulty in that the transfer function usually tends to zero at the boundary of the band while the Fourier transform of the noise, hence that of g_r , does not, or tends to zero in a different way. It follows that $\hat{f}_{\text{inv}}(\omega)$ is divergent or very large at the boundary of the band. We conclude that its inverse Fourier transform does not exist or, if it exists, is affected by large artifacts due to noise propagation. The latter is the typical situation in the case of digital images. In Fig. 1 we give the result of a numerical simulation showing the typical effect produced by the inverse filter. The object is a beautiful picture of a galaxy recorded by the Hubble Space Telescope (HST), while the PSF is a computed one describing the blurring of HST before installation of the optics correction. The blurred image is obtained by convolving the object with the PSF and by adding white noise. The restored image produced by the inverse filter is completely corrupted by noise.

The inverse filter provides a solution which fits the data in the best possible way and therefore also fits the noise in the frequency domains where the signal is weakly transmitted by the imaging system. This can be achieved at the cost of an energy (L^2 -norm) of the solution which is too large. Therefore, such a conclusion suggests that one must search for a reasonable compromise between data fitting and energy of the solution. This is the basic idea of regularization theory, at least in its most simple form. The mathematical formulation is obtained by looking for objects which minimize the functional:

$$\Phi_\mu(f) = \|K * f - g_r\|^2 + \mu \|f\|^2 \quad (6)$$

where μ , the so-called regularization parameter, is a parameter controlling the trade-off between data fitting and energy of the solution: when μ is small, the data fitting is good and the energy is large while, when μ is large, the data fitting is poor and the energy is small.

For a given μ , the function f_μ which minimizes the functional of Eq. (6) is called the regularized solution of the problem. It is easy to show that its Fourier transform is given by

$$\hat{f}_\mu(\omega) = \frac{\hat{K}^*(\omega)}{|\hat{K}(\omega)|^2 + \mu} \hat{g}_r(\omega) \quad (7)$$

Fig. 1 Illustrating the effect of the inverse filter: (a) Image of the Circinus galaxy taken on 10 April 1999, with the Wide Field Planetary Camera 2 of the Hubble Space Telescope; (b) the PSF used for blurring the RGB components of the image (here shown in red); (c) the blurred image obtained by convolving the components of the image in (a) with the corresponding PSFs and adding noise; (d) the restoration obtained by applying the inverse filter to the three components of (c). Part (a) courtesy of NASA/Space Telescope Science Institute.

The regularized solutions form a one-parameter family of functions. When μ is small these functions are strongly contaminated by noise whose effect is gradually reduced when μ increases. For too large values of μ , one re-obtains blurred versions of the original object.

Such behavior is illustrated by the sequence of regularized solutions given in Fig. 2 and corresponding to the example of Fig. 1. The regularization parameter increases starting from left to right and from top to bottom. Its values are $\mu=0$ (inverse filter), 0.001, 0.01, 0.05, 0.1, and 0.5 (the noise is of the order of a few percent and the PSF is normalized in such a way that the sum of all its value is 1). The sequence makes evident the well-established theoretical result of the existence of an optimal value of the regularization parameter. Such an optimal value can be determined in the case of numerical simulations as that represented in Fig. 2. However, its estimation in the case of real images is more difficult. Several methods for the selection of μ have been proposed. We only mention the so-called discrepancy principle. It consists of determining the value of μ , such that the value of the discrepancy functional at f_μ , $\varepsilon^2(f_\mu)$ coincides with an estimate of the energy of the noise. In other words, the data are fitted with an accuracy comparable with their uncertainty.

As shown by Eq. (7), the regularized solution has the same band Ω of the imaging system, because $\hat{K}^*(\omega)$ is zero outside Ω . As is known, a band-limited function can be represented in terms of its samples taken at a rate which is roughly proportional to the size of the band. This is the content of the famous Shannon sampling theorem (more precisely its 2D extension). On the other hand, the sampling distance can be taken as a measure of the resolution provided by the restored image so that one concludes that the restoration method discussed above does not produce an improvement of the resolution of the imaging system. It certainly produces an improvement of the quality of the image which makes possible a visual verification of that resolution.

In many circumstances, the term super-resolution is used for describing methods which allow an improvement of resolution beyond the limit provided by the sampling theorem. Therefore, a super-resolving method must produce a restored image with a band broader than that of the imaging system. Therefore, super-resolution is related to the problem of out-of-band extrapolation.

Such an approach was already proposed in the 1960s, when it was observed that the Fourier transform of an object with a finite spatial extent (all objects have this property) is analytic; then the theorem of unique analytic continuation implies that the Fourier transform of the object can be determined everywhere from its values on the band of the imaging system.

Fig. 2 Illustrating the effect of the regularization parameter. The blurred image is that shown in [Fig. 1\(c\)](#). The sequence is obtained by increasing the value of the regularization parameter: (a) $\mu=0$ (inverse filter); (b) $\mu=0.001$; (c) $\mu=0.01$; (d) $\mu=0.05$; (e) $\mu=0.1$; (f) $\mu=0.5$. It is evident that the best restoration is that shown in (c).

Unfortunately this problem is ill-posed, so that out-of-band extrapolation is not feasible in practice. Only recently it has been recognized that a considerable amount of super-resolution is possible when the spatial extent of the object is not much greater than the resolution distance of the instrument. For example, super-resolving methods could be used for detecting unresolved binary star in astronomical images.

The important point is that a super-resolving method must implement explicitly the finite extent of the object: the domain of the object must be estimated and the method must search for a solution which is zero outside this domain. This introduces an important question in object restoration and, more generally, in the theory of inverse problems, namely the design of regularized solutions satisfying additional conditions (constraints). This question is also important from the theoretical point of view: the problem is ill-posed because of insufficient information on the object as transmitted by the imaging system; the use of additional constraints reduces the class of the solutions which are compatible with the data and therefore can improve the restoration. This is the use of a priori information in the solution of inverse problems.

A constraint which has been widely investigated and used is the positivity of the solution, i.e., all the values of the restored image must be positive or zero. The physical meaning of the constraint is obvious. Its beneficial effect is to reduce ringing artifacts which affect the regularized solutions previously discussed, in cases where the object contains bright spots over a black background or sharp intensity variations from zero to some positive value. The ringing is essentially related to the well-known Gibbs effect in the truncation of the Fourier series.

The requirement of positivity is the requirement of a particular lower bound on the values of the solution. Therefore, one can consider more general constraints in requiring a given lower and/or upper bound on the values of the solution, eventually combined with a constraint on the domain to produce, for instance, a super-resolved positive solution. The most general form of these constraints requires that the solution belongs to a given closed and convex set C in some functional space. A general method producing regularized solutions in a convex set is an iterative method which is essentially a gradient method for the minimization of the least-squares functional, with a projection on the set C at each iteration. In the case of object deconvolution, the least-squares functional is that given in Eq. (4) and the method has the following form: if f_k is the result of the k -th iteration, then f_{k+1} is given by

$$f_{k+1} = P_C[f_k + \tau K^T * (g_r - K * f_k)] \quad (8)$$

where P_C is the convex projection onto the set C , τ is a relaxation parameter and $K^T(x) = K(-x)$. In general, the algorithm, known as the projected Landweber method, is initialized with $f_0 = 0$. An important property is that it has a regularization effect, in the sense that iterations must not be pushed to convergence but stopped after a suitable number of iterations to avoid strong noise contamination. In Fig. 3 we compare, in a specific example, the result obtained by means of the linear regularization method and that obtained by means of the projected iterative method with a lower and upper bound on the solution. The reduction of ringing is evident.

Among the methods producing positive solutions we must mention the most popular one in astronomy, the so-called Richardson–Lucy method, which is an iterative method for Maximum-Likelihood estimation. If the PSF has been normalized in such a way that the sum of all its values is one, it takes the following form:

Fig. 3 Illustrating the effect of constraints on image restoration: (a) Image of the Earth taken during the Apollo 11 mission; (b) blurred image of (a) obtained by assuming out-of-focus blur and adding noise; (c) optimal restoration provided by the regularization method; the ringing around the boundary of the Earth is evident; (d) optimal restoration obtained by means of the projected Landweber method with a lower and an upper bound on the solution at each iteration. Part (a) courtesy of NASA.

$$f_{k+1} = f_k \left(K^T * \frac{g_r}{K * f_k} \right) \quad (9)$$

The method is normally initialized with a uniform image and it must not be pushed to convergence to avoid noise amplification. Another algorithm suggested by statistical arguments and producing positive solution is the so-called Maximum Entropy Method (MEM).

The image restoration methods described above have wide applications both in microscopy and astronomy. For instance, the minimization of the functional Eq. (6), with the additional constraint of positivity, has been used for deconvolving images in microscopy to reduce the effect of the missing cone. On the other hand, the Richardson–Lucy method was widely used for deconvolving the images of HST before installation of corrective optics.

Nowadays, image deconvolution is becoming more important for the ground-based telescopes equipped with adaptive optics. Indeed, even if adaptive optics is able to provide a considerable compensation of the atmospheric blur, a further improvement can be obtained by deconvolving the detected images. The PSF is provided by the image of a suitable guide star.

Finally, it is worth mentioning the Large Binocular Telescope, in construction on the Mount Graham in Arizona, because this instrument requires image restoration methods for a full exploitation of its imaging properties. The telescope (Fig. 4) consists of two 8 m mirrors on a common mount: both mirrors are equipped with adaptive optics and are combined interferometrically to reach the resolution of a 22.8 m mirror in the direction of the baseline. The telescope can be rotated to record images of the same astronomical target with different orientations of the baseline, i.e., the line joining the centers of the two mirrors. Finally the images must be processed by means of multiple images deconvolution methods to obtain a unique high-resolution image, equivalent to that produced by a 22.8 m mirror.

The applications of inverse problems with major social impact are in the area of medical imaging. The spectacular success of X-ray computerized tomography (CT), invented by GH Hounsfield at the beginning of the 1970s, has stimulated the development of other imaging modalities, based essentially on the same principle, such as positron emission tomography (PET) and single photon emission computerized tomography (SPECT). Computed images are also provided by magnetic resonance imaging (MRI). In such a case, however, the computational problem is rather simple since it consists essentially in Fourier transform inversion.

The basic principle of X-ray CT is described as a finely collimated source S (see Fig. 5(a)) emitting a pencil of X-rays which propagates through the body along a straight line L up to a well collimated receiver R . If we know both the intensity I_0 of the source and the intensity I detected by the receiver, the logarithm of the ratio I_0/I is the integral of the linear attenuation function (roughly proportional to the density function of the body) along the line L . If the source and the receiver are moved along two parallel lines, having direction θ and defining the plane Π (in practice a planar slice of the body under consideration), one obtains the integrals of the linear attenuation function $f(\mathbf{x})$ along all parallel lines orthogonal to θ . The scanning variables in the plane Π are defined in Fig. 5(b): φ is the angle formed by the unit vector θ with the x -axis and s is the signed distance between the origin and the integration line L . The integrals along all parallel lines orthogonal to θ define a function of s which is called the projection of $f(\mathbf{x})$ in the direction θ :

$$P_\theta(s) = \int_{-\infty}^{+\infty} f(s \cos \varphi - u \sin \varphi, s \sin \varphi + u \cos \varphi) du \quad (10)$$

The set of the projections of $f(\mathbf{x})$ for all possible θ is called the Radon transform of $f(\mathbf{x})$, in honor of the mathematician Johann

Fig. 4 Picture of the Large Binocular Telescope (LBT) in construction on the Mount Graham in Arizona. It consists of two mirrors on the same mount. The images of the two mirrors are combined interferometrically to produce a high-resolution image in the direction of the line joining the centers of the mirrors (baseline).

Fig. 5 (a) Scheme of the scanning procedure in X-ray tomography: the source(S)–receiver(R) pair is moved along a direction θ orthogonal to the line S–R, defining the plane Π to be imaged; when the scanning has been completed the system is rotated by a certain angle, the scanning procedure is repeated, and so on. (Reproduced with permission from Bertero M and Boccacci P (1998) *Introduction to Inverse Problems in Imaging*. Bristol, UK: IOP Publishing.) (b) Definition of the variables used in the representation of the Radon transform; φ is the angle formed by the S–R line with the x_1 -axis; s is the signed distance between the origin and the integration line (orthogonal to θ); and u is the coordinate on the integration line.

Fig. 6 Picture of a scanner for X-ray tomography. The annular part contains the acquisition and scanning systems.

Radon, who first investigated the problem of recovering a function of two variables from its line integrals. Today, such a problem is known as Radon transform inversion or object restoration from projections. Sampled values of the Radon transform, i.e., sampled values of the projections for a number of possible directions between 0 and π , are the outputs of the acquisition system of the medical equipment known as CT-scanners (Fig. 6). Their data-processing system contains the implementation of an algorithm for Radon transform inversion and the final result is a set of computed images providing maps of slices of the human body.

Fig. 7 (a) Picture of a brain slice; (b) the corresponding sinogram. As explained in the text, the sinogram is a gray-level representation of the Radon transform in the s, φ plane. Each horizontal line in (b) corresponds to a projection of (a).

The plot of the Radon transform of f in the (s, φ) -plane, obtained by representing its values as gray levels, is called the sinogram of f . In Fig. 7, we give the image of the sinogram of a brain slice. The horizontal rows provide representations of the projections of the phantom. In the image, the angle φ defining the direction θ takes values between 0 and 2π while the variable s takes values between $-a$ and a , if a is the radius of a disc containing the phantom. As is evident, the sinogram is symmetric with respect to the point $(0, \pi)$. Each point in the rectangle corresponds to a straight line crossing the phantom and the straight lines through a fixed point of the phantom describe a sinusoidal curve in the (s, φ) -plane. This property has given rise to the name sinogram.

The sinogram is, in a sense, the image of the body slice under investigation, as provided directly by a CT-scanner. However, an inspection of this image does not easily provide information about the body. Therefore, it must be processed to obtain a more significant image. Radon transform inversion is an example of inverse and ill-posed problem and its solution must be treated with extra care.

The crucial point in Radon transform inversion is the Fourier slice theorem, whose content is the following: the Fourier transform of the projection in the direction θ of the function f , is the Fourier transform of f on the straight line passing through the origin and having direction θ :

$$\hat{P}_\theta(\omega) = \hat{f}(\omega\theta) \quad (11)$$

This theorem clarifies the information content of CT data: each projection provides the Fourier transform of the function f along a well-defined straight line in the plane of the spatial frequencies. It is also the starting point for deriving the basic algorithm of data inversion in tomography, the filtered back-projection (FBP). It is obtained from Fourier transform inversion in polar coordinates and is a two-step algorithm: the first step is a filtering of the projections by means of a ramp-filter; the second is the back-projection of the filtered sinogram. More precisely the two steps are as follows:

- *Filtering*: for each θ the projection $P_\theta(s)$ is replaced by a filtered projection given by

$$Q_\theta(s) = \int_{-\infty}^{+\infty} |\omega| \hat{P}_\theta(\omega) e^{i\omega s} d\omega \quad (12)$$

where the multiplication by the ramp filter $|\omega|$ derives from the Jacobian of polar coordinates;

- *Back-projection*: this operation is the dual of the projection operation: indeed the projection assigns to a straight line L with coordinates (s, φ) , hence to a point of the domain of definition of the Radon transform, the integral of f along L ; on the other hand, the back-projection assigns the value of the Radon transform at (s, φ) to all points of the straight line L with the same coordinates (a pictorial representation of projection and back-projection is given in Fig. 8); as a consequence the back-projection operator $R^\#$ assigns to each point $\mathbf{x}$ the sum (integral) of all values of the Radon transform corresponding to straight lines passing through $\mathbf{x}$:

$$R^\# P_\theta(\mathbf{x}) = \int_0^{2\pi} P_\theta(x \cos \varphi + y \sin \varphi) d\varphi \quad (13)$$

The back-projection operator, when applied directly to the projections as in Eq. (13), provides a blurred image of f ; in order to get a satisfactory restoration it must be applied to the filtered projections $Q_\theta(s)$. This point is illustrated in Fig. 9.

We point out that the ramp filter introduced in Eq. (12) amplifies the high frequency components of the projections hence the noise corrupting these components. This remark clarifies that Radon transform inversion is an ill-posed problem and requires some kind of regularization. This is obtained by introducing an additional low-pass filter which reduces the effect of the high frequencies. The most frequently used combination of ramp and low-pass filter is the so-called Shepp–Logan filter.

Fig. 8 (a) The effect of the projection operation is shown by drawing the projections of a circular phantom corresponding to three directions. (b) shows the result obtained by applying the back-projection operation to the three projections given in (a). It is evident that the picture provided by this operation has a maximum on the domain of the circular phantom.

Fig. 9 Illustrating the effect of the filtered back-projection. Shown here is: a slice of the so-called Shepp–Logan phantom; the corresponding sinogram (indicated by the arrow CT scanner); the filtered sinogram (indicated by the arrow filtering); the restorations obtained by applying the back-projection operation both to the original sinogram and to the filtered sinogram.

X-ray tomography is also called transmission computerized tomography (TCT) because the image is obtained by detecting the X-rays transmitted by the body. It provides information about anatomical details of human organs because the map of the linear attenuation function is essentially the map of the density of the tissues.

A different type of information is obtained by the so-called emission computerized tomography (ECT) which is based on the administration of radio-nuclide-labeled agents known as radio-pharmaceuticals. Their distribution in the body of the patient depends on factors such as blood flow, metabolic processes, etc. Then a map of this distribution is obtained by detecting the γ -rays produced by the decay of the radio-nuclides. Therefore, ECT yields functional information, in the sense that the images produced by ECT show the function of the tissues of the organs.

Two different modalities of ECT are usually considered:

- single photon emission computerized tomography (SPECT), which makes use of radio-isotopes where a single γ -ray is emitted per nuclear disintegration;
- positron emission tomography (PET), which makes use of β^+ -emitters, where the final result of a nuclear disintegration is a pair of γ -rays, propagating in opposite directions, produced by the annihilation of the emitted positron in the tissues.

In both cases it is necessary to detect the γ -rays coming from well-defined regions of the body and, to this purpose, different methods are used in each case.

In SPECT, the discrimination of the γ -rays is obtained by means of a collimator, consisting of holes in a large lead slab covering the crystal detector face. In PET the collimation is obtained by means of pairs of detectors in coincidence. This technique, which is also called electronic collimation, is more accurate than the physical collimation used in SPECT and allows the design of systems with a great efficiency.

The basic reconstruction method in TCT, namely FBP, is often used in the reconstruction of SPECT and PET data. However, several corrections are necessary in practice. The principal ones are due to the collimator blur and to the scattering of photons in the body. If one develops a more accurate model of data acquisition by taking into account these effects, then the restoration problem implies the inversion of a very large matrix which is sparse and ill-conditioned. To this purpose iterative regularization methods are used such that the basic operation required at each step is matrix-vector multiplication. Other imaging modalities, which have been proposed for medical applications, are electrical impedance and microwave tomography. The underlying inverse problems are basically nonlinear so that the computational cost of the methods for their solution is, in general, too high for clinical applications. However the research in these areas is very active and, therefore, the situation could be improved in the near future.

Adaptive Optics

Introduction

The image quality of a perfect optical system is ideally limited by its diffraction figure. In the real world there are many effects which degrade that physical limit, resulting in poorer image quality at the focal plane. These effects may be static (e.g., time-independent, as, for example, error in the alignment of the optical train) or dynamic (e.g., variable with time, such as optical misalignment introduced by thermo-mechanical distortion). Active and adaptive optics, the topics of this article, are technologies able to correct for the optical aberrations induced by dynamical effects. There are a variety of causes liable for dynamical image degradation, among these time-variable optical misalignments, pointing and tracking errors (for motorized instruments), and atmospheric perturbations. In practice, both atmospheric turbulence and misaligned instrument introduce random spatial and temporal perturbations on the optical beam, distorting the spherical (ideal) wavefront incoming on to the focal plane. This leads to loss of both the diffraction limited condition and image resolution. A typical situation for astronomical application is shown in Fig. 1. A target (a star in this case) emits light whose wavefront, being far from the observing system, can be considered plane. When this wavefront passes through the atmosphere it is distorted with a temporal frequency of the order of hundreds of Hertz. This dynamically distorted wavefront fills the aperture of the optical system and will once more be distorted by the dynamic misalignment of the optical system itself. The final wavefront will be deformed with respect to the ideal (spherical) wavefront.

Dynamic optical misalignment may depend on gravitational and thermal deformation, while pointing error may appear as very slow (drift), slow (wander), or fast (jitter) tilt of the image on the focal plane. Atmospheric perturbations are produced by air turbulence and may be natural (as in the astronomical or satellite tracking cases) or induced by the experiment itself

Fig. 1 Dynamical wavefront aberration.

Fig. 2 Wavefront aberration time-scale and associated aberrations.

(thermal blooming in high power laser applications). All these effects appear on very different time-scales, as shown in [Fig. 2](#). As noticeable, atmospheric turbulence introduces aberrations of all orders, at a frequency above about 1 Hz. Pointing and tracking errors introduce an image tilt with different time-scale. Gravitational effects induce mechanical deformation of the optics, mainly in astronomical applications because of the massive components (the telescope primary mirror in particular). Thermal deformation produces optical misalignment among optical components mainly resulting in defocus. [Fig. 2](#) is purely illustrative, because some effects may produce wavefront aberrations at different frequencies than indicated there. For example, drift may be faster than indicated in the figure, and thermal blooming (a thermal effect) introduces aberrations at a higher frequency, and so on.

The correction of the wavefront errors is usually made by means of devices able to change the phase wave somewhere in the light path. Though the concept for correcting aberrated wavefront at slow or high frequency is the same, for example, the use of one or more deformable elements in the optical path, the technologies developed for each area are quite different: variations at slow frequency (approximately below 0.1 Hz in [Fig. 2](#)) are indicated as quasi-static errors and the techniques developed to overcome them are properly called active optics, while adaptive optics indicates the techniques to overcome the unwanted effects at high frequency (above about 1 Hz in frequency). The frequency value dividing the active from adaptive optics is not well defined and depends on the field of application and its scientific engineering communities. The important point is that a correct use of a combination of the two techniques may ultimately lead to bringing the imaging system close to its diffraction limit.

Slow Corrections: Active Optics

The analysis of the wavefront is required before its correction, and one or more deformable/movable mirrors and their control system, to operate the corrections. A typical system for low frequency correction is shown in [Fig. 3](#). A telescope contains three mirrors (M1, M2, and M3) and an instrument to detect its scientific target, usually placed on its optical axis. The dynamic deformations present in this kind of instrument are mainly third-order spherical (thermal deformation of M1), third-order astigmatism (a saddle-horse deformation of M1 due to gravity when the telescope is pointing away from the zenith), and third-order coma (due to gravitational decentering between M1 and M2). Since a telescope has a tracking system some pointing error may be present, causing motion of the image in the focal plane. The observation of an off-axis target (typically a star for astronomical applications) is made to measure the deformations of the incoming wavefront by means of a wavefront sensor (WS) system. This step is completed using some of the wavefront sensing technique described elsewhere in this encyclopedia. The WS must measure the information on the wavefront distortion with adequate spatial resolution to compensate for aberrations across the full aperture of the system. Once the wavefront distortion has been measured by the WS, the needed corrections are sent to the control system which apply the appropriate mirror deformation/movements. In the example of [Fig. 3](#) only the primary mirror (entrance pupil) is deformable and it is used for correcting spherical and astigmatism aberrations. M2 is used to compensate the decentering coma by means of lateral displacement. M3 may be tilted to correct for low-frequency pointing errors. In astronomical applications active optics is essential for telescopes with primary-mirror diameters larger than approximately four meters which cannot be manufactured rigidly at reasonable cost. Active optics requires a thin deformable or a segmented primary mirror maintained on the correct shape at every elevation. Using this method, low-frequency correction has been achieved to date in telescopes with primary mirrors of the order of ten meters.

Fig. 3 A typical system for correcting low-frequency dynamical aberrations (active optics).

Fig. 4 A typical setup for correcting high-frequency dynamical aberrations (adaptive optics).

Fast Corrections: Adaptive Optics

It is clear that corrections at high frequency are impossible using the approach discussed above, because of the large dimensions and weight of the mirror and the low response time required. For an adaptive correction it is necessary to image a smaller system pupil in the optical train and make the active correction of the wavefront. A typical configuration is shown in Fig. 4. The light from the telescope focal plane (corrected for low frequency errors by means of active optics) is collimated and a pupil is located in this beam. Behind the active mirror a beamsplitter is used to send part of the light into the WS and measure wavefront distortions. The analysis results are sent to the control system which performs the active mirror deformation for the wavefront compensation. If the WS and the control system are sufficiently fast (typically faster than the time-variations of the wavefront distortion), this system is able to produce a plane wavefront which can be focused at the diffraction limit of the system. For this reason adaptive optics are often referred to as real-time system.

The seminal paper on the adaptive optics concept was written by H.W. Babcock of the Mount Wilson and Palomar observatories in 1953. Since then a great improvement has been made, especially in military and astronomical fields. In recent years, however, many applications of adaptive optics have developed in fields different from traditional ones, such as precision manufacturing by means of high-power lasers, telecommunications, aero-optics, medical physics, and ophthalmology.

We describe adaptive optics with particular reference to astronomical applications. We provide a brief description of other applications at the end of this article.

Imaging Through the Atmosphere

The optical effects of the atmospheric turbulence are due to local temperature variations that induce fluctuations in the refractive index of air. The refractive index changes depend on the air density as well as the range of the temperature variations. Air density is highest at sea level and decreases exponentially with altitude. Optical effects of turbulence decrease with the altitude of the site, the reason for locating astronomical telescopes on mountains. The effects of turbulence on a point source image are depicted in Fig. 5. Hereafter we consider an ideal telescope, for example, one without need for active correction at low frequencies. We consider the source 1 (continuous line). The radiation emitted by the source is a spherical wavefront that can be treated as a plane, because of the very long distance to the Earth's atmosphere.

In absence of wavefront distortion, the angular diameter of the image (Airy disk), is approximately $2.44\lambda/D$, with λ the wavelength of the observation and D the telescope aperture (the mirror diameter). In this case the image is said to be diffraction limited, and it is the best possible performance for the observation. This is the performance of a space-based ideal telescope.

Fig. 5 Imaging through the atmosphere.

In the presence of the atmosphere the incoming wavefront is distorted by the turbulence and when it reaches the telescope aperture it is no longer a plane (see in Fig. 5). The so-called Fried's parameter r_0 (also called atmospheric coherence length) is the most common parameter used to quantify the distortion effects of atmospheric turbulence. It is defined as the distance over which the wavefront phase is highly correlated (in this way it provides a measure of the turbulence scale size). For an undistorted plane wave, r_0 is infinity, while for atmospheric distortion it typically varies between 5 cm (bad sites) and 20 cm (excellent sites). We depict Fried's parameter schematically in Fig. 5, as bubbles of dimension r_0 in the turbulent layer (referred to as Fried's cells). r_0 is a statistical parameter, which depends on time and wavelength ($r_0 = r_0(t, \lambda^{6/5})$). Its variability with time may be considerable, sometimes changing by a factor of 2 within a few seconds. A small telescope, with a diameter less than r_0 , will always operate at this diffraction limit. When the r_0 is smaller than the telescope aperture, the angular size of the image is different if we consider long- or short-time exposures. If the exposure time is very short (less than hundredths of a second) it is possible to image a structure in the focal plane (see short exposure image in Fig. 5). This structure, which varies with time, is due to high-order wavefront distortions that occur within the aperture. The short exposure image is broken into a large number of speckles of diameter $2.44\lambda/D$, which are randomly distributed over a circular region of approximately $2.44\lambda/r_0$ in angular diameter. A lower-order wavefront distortion is correlated with the size of the largest disturbances produced by atmospheric turbulence (the so-called outer scale) which varies considerably (from 1 m to over 1 km). Such disturbances produce a time-dependent tilt of the overall wavefront that causes fluctuations in the angle of arrival of the light from a star and randomly displace the image. For D of the order of the Fried parameter r_0 , image motion dominates, and a simple tip-tilt mirror (not just deformable) provides useful correction. For D greater than r_0 , speckles dominate and a deformable mirror is necessary to account for the wavefront distortion. For long exposures the dimension of the image is determined by the ratio λ/r_0 rather than $2.44\lambda/D$. The angular resolution is diminished due to the atmospheric turbulence (see Fig. 5). For a 4 m telescope, atmospheric distortion degrades the spatial resolution by more than one order of magnitude compared to the diffraction limit, and the intensity at the center of the star image is lowered by a factor of 100 or more. Even at the best astronomical sites, ground-based telescopes observing at visible wavelengths cannot, because of atmospheric turbulence alone, achieve an angular resolution better than telescopes of about 20 cm diameter.

Most of the distortions imposed by the atmosphere are in the wave-phase and an initially plane wavefront traveling 20 km through the turbulent atmosphere accumulates, across the diameter of a large telescope, phase errors of a few micrometers.

Turbulence is distributed along the propagation path through the atmosphere, and then the wavefront errors become uncorrelated as the field angle increases. This effect is known as angular isoplanatism and is one of the major limitations to the astronomical adaptive optics. The structure becomes completely uncorrelated out of the isoplanatic angle, approximately equal to r_0/H , where H is the altitude of the turbulence layer. This decorrelation is sketched in Fig. 5, where the short exposure images for objects 1 and 2 have different speckles structure.

In Earth's atmosphere significant turbulence occurs at altitudes up to 20 km, often with large peaks in the vicinity of the tropopause, at around 10 km there exist, in practice, more than one parameter H in Fig. 5, one for each turbulence layer. This three-dimensional distribution of the turbulence considerably restricts the angle over which adaptive compensation is effective and leads to the design of multiconjugate adaptive optics, as we next explain.

Adaptive System Design

As stated above, an active system is composed of at least one wavefront sensor and one deformable mirror. Typically, the wavefront is corrected by making independent tip, tilt, and piston movements of the deformable mirror surface, as shown in Fig. 6. As a rule of thumb, a deformable mirror used for atmospheric correction should have one actuator for each Fried's cell, such that the total number of actuators should be equal to the number of Fried's cells filling the telescope aperture, i.e., D^2/r_0^2 . For instance, a near-perfect correction for an observation in visible light ($0.6 \mu\text{m}$) with an 8 m telescope placed in a good astronomical site ($r_0 = 20 \text{ cm}$), would require a deformable mirror with approximately 6400 actuators in its adaptive optics system. Recalling that r_0 is strongly dependent on the wavelength (i.e., proportional to $\lambda^{6/5}$), similar performance in the infrared at $2 \mu\text{m}$ requires only 250 actuators. This is one reason why adaptive correction is easier in the infrared. A large number of Fried's cells requires a similarly large number of subapertures in the wavefront sensor. Commonly used WSs are based on modifications of the classic Hartmann screen test or of curvature type. In the former case the adaptive device is made with individual piezoelectric actuators (see Fig. 6), while in the latter the correction is achieved with a bimorph adaptive mirror, made of two bonded piezoelectric plates. With both

Fig. 6 A sketch of a deformable mirror.

methods, wavefront sensing is done on a reference off-axis object (Fig. 3), or even on the observed object itself (Fig. 4) if it is bright enough. In the former case the angular distance of the reference object must fall inside the isoplanatic angle and must be sufficiently luminous. In typical astronomical sites the isoplanatic angle at a wavelength of $0.6\ \mu\text{m}$ is $\sim 5\ \text{arcsec}$, while it can be $\sim 20\ \text{arcsec}$ at $2\ \mu\text{m}$. This is an additional reason why the adaptive optics system is most efficient in the infrared range. Correction in the visible requires a reference star approximately 25 times brighter than in the infrared. Most current astronomical systems are designed to provide diffraction-limited images in the near-infrared ($1\ \text{to}\ 2\ \mu\text{m}$) with the capability for partial correction in the visible. However, some military systems for satellite observations do provide full correction in the visible on at least $1\ \text{m}$ class telescopes.

The control system is generally a specialized computer that calculates, from the WS measurements, the commands to send the actuators of the deformable mirror. The calculation must be performed quickly (within $0.5\ \text{to}\ 1\ \text{ms}$), otherwise the state of the atmosphere may have changed making the wavefront correction inaccurate. The required computing power can exceed several hundred million operations for each command set sent to a 250 actuator deformable mirror. As in active optics systems, zonal or modal control methods are used. In zonal control, each zone or segment of the mirror is controlled independently by wavefront signals that are measured for the subaperture of that zone. In modal control, the wavefront is expressed as the best-fit linear combination of polynomial modes of the wavefront distorted by the atmospheric perturbations.

Future Development

As explained above, a convenient method for measuring the wavefront distortion is to look for an off-axis reference star (also known as natural guide star, NGS) within the isoplanatic angle. However, it is generally impossible to find a bright reference star close to an arbitrary astronomical target. Conditions are far better in the infrared than in the visible because atmospheric turbulence (and in particular its high spatial frequencies) is, for a given AO correction, less pronounced at longer wavelengths. The spatial and temporal sampling of the disturbed wavefront can be reduced, which in turn can permit the use of fainter reference stars. Coupled with the larger isoplanatic angle in the infrared, this gives a much better outlook for AO correction than in the visible.

Nevertheless, even for observations at $2.2\ \mu\text{m}$, the sky coverage achievable by this technique (equal to the probability of finding a suitable reference star in the isoplanatic patch around the chosen target) is of the order of $0.5\ \text{to}\ 1\%$. It is therefore unsurprising that most scientific applications of AO have to date been limited to the study of objects which provide their own reference object. The most promising way to overcome the isoplanatic angle limitation is by the use of artificial reference stars, also referred to as laser guide stars (LGS). These are patches of light created by the back-scattering of pulsed laser light of sodium atoms in the high mesosphere or by molecules and particles located in the low stratosphere. The laser beam is focused at an altitude of about $90\ \text{km}$ in the first case (sodium resonance) and $10\ \text{to}\ 20\ \text{km}$ in the second case (Rayleigh diffusion). Such an artificial reference star can be created as close to the astronomical target as desired, and a wavefront sensor measuring the scattered laser light is used to correct the wavefront aberrations on the target object.

Military laboratories have reported the successful operation of adaptive optics devices at visible wavelengths using laser guide star on both a $60\ \text{cm}$ telescope and a $1.5\ \text{meter}$ telescope, achieving an image resolution of $0.15\ \text{arcsec}$. Nevertheless, there are still physical limitations of a LGS. The first problem, focus anisoplanatism, or cone-effect, was realized long ago. Since the artificial star is created at a relatively low altitude, back-scattered light collected by the telescope forms a conical beam, which does not cross the same turbulence-layer areas as light from the astronomical target. This leads to a phase estimation error, which in principle can be solved by the simultaneous use of several laser guide stars surrounding the targeted object. A more significant problem is image motion or tilt determination. Since the paths of the outgoing and returning light rays are the same, the centroid of the artificial light appears to be stationary in the sky, while the apparent position of an astronomical source suffers lateral motions (also known as tip/tilt). The simplest solution is to supplement the AO system and LGS with a tip/tilt corrector set on a (generally) faint close NGS. Performance is then limited by poor photon statistics in the tip/tilt correction.

Adaptive optics with a multicolor laser probe is another concept that has been studied to solve the tilt determination problem of laser beacon based AO. Only applicable to sodium resonant scattering at $90\ \text{km}$, it excites different states of the sodium atoms and makes use of the slight variation in the refraction index of air with wavelength. Its main drawback is the limited returned flux, due to the saturation of mesospheric sodium layer.

The quality of a site for adaptive optics is determined not only by the median seeing, but also by the height and thickness of the turbulent layers (often only a few thin layers dominate). Some adaptive-optics systems can be adapted to correct for turbulence originating at a particular height by using several reference stars. This technique is known as multiconjugate adaptive optics (MCAO) and is still in its infancy. This concept deals with a 3-D view of the atmosphere, and for this reason it is also called turbulence tomography. Several wavefront sensors are needed for tomography. Turbulence tomography is also useful to correct for the cone effect when using LGS. When several deformable mirrors are placed on the appropriate conjugate planes, as shown in Fig. 7, anisoplanatism reduces and the size of the corrected field of view increases. The situation is roughly depicted in Fig. 7, where each turbulent layer (indicated as TL) has a proper conjugated plane (C-TL).

Another challenging optical solution is one of utilizing large secondary adaptive mirrors. This application seems especially interesting at thermal wavelengths, where any additional mirror raises the significant thermal background detected by instruments.

Fig. 7 Conjugated planes of turbulent layers.

Fig. 8 Thermal blooming effect in high-power laser applications.

Other Adaptive Optics Applications

In recent years the adaptive optics technique has been developed in many applications beside astronomy and the military, for example, as in high-power laser welding or cutting, in ophthalmology and in aero-optics.

In high-power laser applications, thermal blooming takes place when laser light is absorbed by the gases and particles that make up the atmosphere. Since energy is conserved, the energy lost by the laser (its intensity diminishes) is gained by the atmosphere that heats up. This inhomogeneity at the boundary of the laser beam generates wavefront distortions by turbulence, as shown in [Fig. 8](#). This means that laser light that passes through the air at a later time interacts with a different atmosphere than the light that passed by earlier. The net effect is that, in the case of a Gaussian laser beam, light following a wavefront which passed at an earlier time, 'sees' a concave lens that deflects the successive rays out of the beam (away from the axis) causing the beam to appear to grow in radius or 'bloom'. Adaptive optics techniques for real-time compensation of blooming in laser beams were developed in the late 1960s. Given the high coherence and monochromaticity of a laser, the technique is more straightforward than for more common white-light applications of the astronomical applications.

Density fluctuations in a compressible shear layer are sufficiently high to cause a time varying index of refraction of the layer. This situation is common in a turbulent flowfield, and the study of the wavefront aberrations induced by this flowfield, when it is of relatively short propagation length in the near-field of the optical system, is referred to as aero-optics. Turbulent flowfield induces various types of degradations in the performances of an optical system. For example the jitter and defocusing of laser-based weapons cause a reduction in the amount of energy delivered to the target. Tracking systems experience bore-site errors and imaging systems experience blurring. Recent work suggests that adaptive optics compensation may successfully overcome these problems.

In ophthalmology the adaptive technique finds application in studying the retina of the eye. In this case the eye itself produces wavefront aberration, and the retina is seen as blurred. Techniques in ophthalmic laser surgery are being developed to use adaptive optics to correct for detected distortions.

In the field of telecommunications, studies are in progress for using adaptive techniques in data transmission between ground-based stations and satellites.

Phase Conjugation and Image Correction

EN Leith, University of Michigan, Ann Arbor, MI, USA

Introduction

Phase conjugation of a wave is a process that has long been recognized. However, the technique for producing high-quality phase conjugation is relatively new. Also, the principal use of phase conjugation, the correction of phase errors in waves that have propagated through phase-distorting media, is relatively new, having originated in holography in the 1960s. Today, phase conjugation is an important area of modern optics. This article describes the conjugation of a wavefield by the process of holography and the holographic phase conjugation method of removing phase distortions from a wavefield, thereby permitting high-quality images to be produced from phase-distorted waves.

The basic meaning of a conjugated wave is explained with the aid of Fig. 1. Fig. 1(a) shows a wavefield propagating to the right. For simplicity, we show only one wavefront, i.e., one contour of constant phase. It is understood that a wavefield consists of a sequence of such wavefronts, with each wavefront differing in phase by 2π from the adjacent one, and separated by the wavelength λ . Of the two points, A and B, on the wavefront, we say that the wavefront at A lags that at B, since when the wavefront crosses a plane normal to the direction of travel, point A of the wavefront crosses that plane behind point B. The wavefield produces, at the plane P, a field $ae^{i\phi}$, where a is the amplitude and ϕ is the phase of the wavefront at the plane P.

We place a phase conjugator in the path of the wave. The wave passes through the conjugator, emerging as a phase conjugated wave, in which the point B, which formerly led point A in phase, now lags behind it by a corresponding amount. This illustrates the basic meaning of the term 'phase conjugation'. This device could be considered as a forward phase conjugator, since the phase conjugated wave travels in the same direction as the original wave.

Next (Fig. 1(b)) we describe a backward phase conjugator. The conjugate wave travels in a direction opposite to that of the incident wave. The conjugate wave emitted by the phase conjugator seems to be identical to the incident wave; we show the two waves to be in coincidence, or more precisely, for purposes of clarity, almost in coincidence. The points A on the two wavefronts coincide, as do the points B. As before, on the incident wave, point A lags behind point B. On the exiting wave, since the wave is traveling in the opposite direction, point B is now lagging point A, i.e., is lagging in phase. In either case, forward or backward conjugation, the wave emerging from the conjugator has the complex amplitude $a(x, y)e^{-i\phi(x, y)}$.

A phase conjugator (backward variety) is like a mirror, in that it obeys the basic mirror law, that the angle of reflection equals the angle of incidence, but in a rather different way, as Fig. 2 shows. In fact, the reflected ray travels back on itself. A simple way to generate a conjugate wave, and one that has been known for a very long time, is with the use of an array of retroreflectors, or corner cubes. As shown in Fig. 3, each ray undergoes two reflections and emerges traveling in exactly the opposite direction, although with some displacement. If we considered the third dimension, there could be three reflections. The amount of displacement depends on where the ray strikes; if it strikes near the apex of the corner cube, the ray displacement will be slight; if at the edge, the displacement is greatest. Thus, the image formed in reflection is degraded. This geometrical degradation is greater for larger corner

Fig. 1 A phase conjugator. (a) shows a forward phase conjugator; (b) shows a backward phase conjugator. For clarity, in (b) the conjugated wave is shown with dotted lines. PC is phase conjugator, and P is the entrance plane of the conjugator.

Fig. 2 Light reflected from mirrors. (a) Light falling on a conventional mirror and being reflected; (b) light reflected from a conjugating mirror; (c) as in (b), except that illustration is with wavefronts instead of rays.

Fig. 3 A ray of light reflected from a retroreflector (or corner cube).

Fig. 4 The holographic process. (a) Making the hologram; (b) reading out the hologram, using a readout beam that duplicates reference beam; (c) reading out with reversal of reference beam.

cubes. Thus, why not make the cubes very small? Then, however, the image is degraded by diffraction effects, since each corner cube constitutes a small aperture. Thus, there is an optimum size for the cubes; if too large, geometrical factors degrade the image; if too small, diffraction effects degrade the image.

Phase Conjugation by Holography

With holography, however, came a method of conjugating a wavefront that yields high-resolution imagery. The holographic process inherently produces a phase conjugate image, as was noted by Gabor in his early papers on holography. The holographic process is illustrated in Fig. 4. For simplicity, we assume the object to be a planar transparency $s(x, y)$. A coherent light wave, generally a plane or spherical wave, passes through the transparency and a diffracted field u is produced at the recording plane P , as in Fig. 4(a). The field u is typically the Fresnel diffraction pattern of the object s , but if the propagation distance is sufficiently great, u could be the Fraunhofer pattern of s . Of course, lenses can be placed between the object and recording planes, thus modifying the diffraction pattern.

The field u is combined with a reference wave u_o , which is generally an off-axis planar or spherical wave. The two beams produce an interference pattern with intensity

$$I = |u_o + u|^2 = |u_o|^2 + |u|^2 + 2\text{Re } u_o^* u \quad (1)$$

where the final term can be written as $u_o^*u + u_o u^*$; the $*$ denotes complex conjugate. The process of forming the interference of the two beams, i.e., forming the intensity of their sum, has generated the conjugate term u^* . When the intensity is recorded, as on photographic film, for example, both terms are stored on the film. Suppose for simplicity that u_o is a plane wave $a_o e^{i2\pi f_o x}$, where a_o is a constant, and $f_o = (\sin \theta)/\lambda$, where θ is the angle that the reference wave makes with the optic axis and λ is the wavelength of the light. Also, u can be written as a product of an amplitude term a and a phase term $e^{i\phi}$, or $u = a e^{i\phi}$. Let the photographic plate, after exposure and development, have a transmittance t proportional to the intensity I , or $t = kI$ with k a constant; this is an oversimplification of the recording process, but preserves the essence of the holographic process. Now let the photographic plate, which after development becomes a hologram, be illuminated with a readout wave that, for simplicity, we let be u_o , a duplicate of the reference wave. Then, the field emerging from the hologram is

$$u_e = u_o k [|u_o|^2 + |u|^2 + u_o^* u + u_o u^*] \quad (2)$$

Only the last two terms are of interest. These can be written as $k|u_o|^2 u$ and $ku_o^* u^*$, respectively, or alternatively, as $ka_o^2 a e^{i\phi}$ and $ka_o^2 a e^{i(4\pi f_o x - \phi)}$. The term $k|u_o|^2 u$ represents a wave that is, to within a constant, identical to the object wave u ; the other term represents a wave that is, to within a constant and a linear phase term, a conjugate of the original wave. The factor $e^{i4\pi f_o x}$ has the physical meaning that the wave is propagating in a direction 2θ given by $\sin 2\theta/\lambda = 2f_o$. The readout waves are shown in Fig. 4(b).

The so-called true wave u and the conjugate wave u^* thus propagate angularly away from each other and from the direct transmitted beam, which carries the uninteresting components $|u_o|^2$ and $|u|^2$.

However, a more suitable way to form the conjugate wave is to illuminate the hologram with a readout wave that is, again, a duplicate of the original reference wave, but propagating in the opposite direction, as in Fig. 4(c). The conjugate wave is now propagating along the z axis, along the path of the original object wave. It is readily shown that this counterpropagating wave is identical in shape to the original object wave recorded by the hologram, except that it travels in the opposite direction, exactly the situation portrayed in Fig. 2. This wave propagates so as to form an image that is, to within a constant, identical to the original object, except for the counterpropagation, which produces a conjugate image $s^*(x, y)$. The image intensity, however, is $|s|^2$, which is identical to the original image intensity.

This conjugate wave was, in the early days of holography, a detriment, since without the use of the off-axis method (reference wave introduced at an angle to the object wave) the two images were inseparable, and the true image could be observed only against the background of the defocused conjugate image. Thus, an out-of-focus image overlaid the true image, making it noisy.

In 1962, the same year that the off-axis reference wave for separating the two images was introduced, a possible use for the conjugate image was suggested. If the original propagation path of the object wave were aberrated, as would occur if the wave propagated through an irregular medium, then the conjugate wave propagating through the medium would undergo a correction and would arrive at the original object position perfectly corrected, resulting in a sharp image, a process sometimes called wavefront healing. The idea lay dormant for 3 years, until in 1965, experimental demonstration of this idea was reported. In one case, the object was a transparency containing opaque lettering against a transparent background and the inhomogeneity was a piece of frosted glass, which resulted in extremely severe aberrations, so that the object wave, having traversed the diffuser, was no longer capable of forming an image. However, when the distorted wave was recorded holographically, conjugated, and sent back through the same diffuser, the result was a highly legible image.

The principle of wavefront healing is illustrated in Fig. 5, when the inhomogeneity is an extended, or three-dimensional, structure. A point object O sends a spherical wave into the inhomogeneity. As the wavefront propagates, it becomes distorted, and loses its sphericity. When it emerges from the inhomogeneity, the wavefront is highly distorted. The wave is conjugated at the conjugator C and emerges as a back-propagating wave that retraces the original wave path through the inhomogeneity, gradually losing its aberrations and looking more like a spherical wave. When it emerges from the inhomogeneity, it is a perfect spherical wave that converges to a point image that coincides with the original object. At each plane throughout the inhomogeneity, the back-propagating conjugate wave (dashed lines) has the same shape as did the original wave when it crossed that plane (solid line).

Fig. 5 The wavefront healing process. C is the conjugator, I is the inhomogeneity, and O is a point object.

This interesting wavefront healing property of holographic phase conjugation was the beginning of a new branch of optics, called phase conjugation, giving rise to a number of applications. However, the holographic method had the problem that it did not occur instantaneously, but had to await the processing of the photographic film on which the hologram was recorded. This delay limited the range of potential applications. Later, in the 1970s, nonlinear crystals became available that did the equivalent of holography, but in real time, or near real time – a process known as four wave mixing. There are yet other types of real-time phase conjugators with nonlinear devices.

Pseudoscopic Image

As long as the object is only two-dimensional, a function of x and y only, with no extent along the axial dimension, z , the intensity distribution of the true and conjugate images is identical. The conjugateness, being a pure phase phenomenon, disappears when the observable is the image intensity $|s|^2$, and not the complex amplitude s . Since the intensity is always the observable, whether the image is viewed by eye, or with a camera, the conjugateness generally is of no significance.

However, when the object for holography is three-dimensional, the situation is different, and the conjugate image exhibits some strange properties. These arise from conflicting cues pertaining to the three-dimensionality of the image. To explain, we review some basics about how a three-dimensional world is perceived by a viewer. First, there is the stereo effect, resulting from the viewer having two eyes, with each eye seeing an object from slightly different positions, a phenomenon called binocular disparity. The mind uses this stereo effect to perceive three-dimensionality. But there are other cues that also contribute to perception of three-dimensionality. Another is parallax; as the viewer moves his head, objects farther from the observer change their angular position more slowly than objects close by. The observer can sense the three-dimensionality of an object, even with only one eye, by moving the head, thereby inducing parallax. Also, there is interposition, whereby near object portions block the viewing of object portions lying behind them, again giving a sense of depth. There are still other cues, more subjective, such as perspective, parallel lines converging toward infinity, shadowing, etc. With these observations in mind, we consider the hologram under illumination and the two images that it forms (Fig. 6). As depicted in Fig. 6, these two images lie in mirror symmetrical positions relative to the hologram. Both images have the same side facing the hologram. It must be this way, because when the hologram was recorded, it was side *a* that faced the recording plane. And both images must therefore have side *a* closer to the hologram.

When a viewer observes the true image (a virtual image), he views it looking through the hologram, and he sees the image at the position where the original object was when the hologram was recorded, and it is, in its visual properties, indistinguishable from the actual object; it has all of the three-dimensional and the parallax properties that the original object would exhibit. However, when the viewer observes the conjugate image, he must view it from the side of the image opposite from the hologram, i.e., he views the image from the back side. When a viewer observes the conjugate image, he sees it from the back side (side *b*). All of the above cited cues are in agreement about the orientation of the image, viz., that side *b* is closer to the observer than is side *a*. That is, all cues but one. The conjugate image is formed as the hologram recording plate saw it, with side *a* being closer. Thus, all interpositions are formed with the same relation that the object had with respect to the recording plate. The side *a* is the part of the object that was closer to the hologram, so that when interpositions occur, side *a* blocks side *b*. Since the observer thus sees side *a* partially obscuring side *b*, he must conclude that side *a* is closer than is side *b*. However, this observation is in direct conflict with the other cues, especially the stereo and the parallax cues, which are themselves strong cues, as is the interposition cue. The conflict of these cues, with two of them interpreting the image as being formed with one depth orientation, the other with the opposite, gives a number of strange effects. For example, as the viewer moves his head so as to induce parallax, the object appears to rotate. If the image is that of a human head, for example, the observed effect is that as the viewer changes his position, the head appears to

Fig. 6 Formation of the true and conjugate images from a hologram.

rotate in synchronism with the observer, as if the image had its gaze fixed on the viewer, an effect that is often perceived as being eerie.

Similarly, if the object were two flat plates, (Fig. 7) in the situation depicted, the planes have no overlap, i.e., no interposition, as seen by the observer. And the observer unequivocally perceives plate A as being closer than plate B. However, if the viewer moves his head to a position where interposition occurs, the conflict of cues arises, A becomes partially blocked by B, which is quite correct as observed at the position of the hologram, but is quite incorrect from the viewer's vantage point. The result of this conflict is that the viewer, who previously perceived the three-dimensionality, now sees the three-dimensionality perception suddenly collapse, and the sense of three-dimensionality is lost. Other strange perception anomalies can also be produced. Such images, with conflicting depth cues, are called pseudoscopic, as opposed to orthoscopic images, where the cues do not conflict.

One Way Phase Conjugation

A significant limitation of phase conjugation aberration correction is that the image and object are on the same side of the inhomogeneity. One would usually want them to be on opposite sides. In a modified form of the phase conjugation process, shown in Fig. 8, this result is achieved. The first step of the process is carried out by passing a plane wave, instead of the object wave, through the inhomogeneity. This plane wave originates from a point source located at the focal plane of a collimating lens.

Fig. 7 Pseudoscopic conjugate image formed from an object consisting of two plates. The viewer V perceives plate A as being closer than B and there are no conflicting cues, since there is no interposition. However, if the observer moves his head upward, there is partial interposition, thus conflicting cues, and the sense of three-dimensionality is lost.

Fig. 8 One-way phase conjugation. Top: Making the hologram. Bottom: The viewing process. We show three points on the object. The center point forms a well-corrected image, but the other two points produce imperfectly corrected images.

The plane wave thus carries information about the inhomogeneity to the recording plate, where it is combined with a reference wave and a hologram of the distorted plane wave is recorded. Thus, information about the phase defect is stored on the hologram.

Next, the hologram is read out, not with a counterpropagating replica of the reference wave as before, but instead with an object-bearing wave that passes through the hologram. This wave emerges from the hologram and now has on it the recorded aberration information. As it counterpropagates along the path of the original object wave, it passes through the inhomogeneity, whereupon the aberration is cancelled and a corrected image forms at the focal plane of the collimating lens, where previously the point source had originated. The goal is achieved; the object and the corrected image are now on opposite sides of the inhomogeneity.

This correction is only approximate. To explain, we think of the object as being a collection of many points. The radiation from each point is converted into a plane wave by the lens, with different object points producing plane waves propagating at different angles. These plane waves then impinge on the hologram and emerge with each one bearing the aberration stored on the hologram. They continue on their paths and enter the inhomogeneity. The plane wave component, whose path direction matches that of the reference wave used in recording the hologram, will emerge from the inhomogeneity as a perfectly corrected wave, thus forming a well-corrected point image at the position of the original point radiator. However, another plane wave component, traveling in an incorrect direction, will be laterally displaced from the proper position for entering the inhomogeneity, and the aberration correction will be imperfect, the degree of imperfection being in direct relation to this displacement error. The displacement error is the product of the angular error and the propagation distance between hologram and inhomogeneity. If the inhomogeneity is slowly varying as a function of x and y , and if the object does not have a large extent, so that the range of angles is small, the image degradation will be small.

If the last two conditions do not apply, two options are available. First, the distance between inhomogeneity and hologram can be reduced, either by bringing the hologram closer to the inhomogeneity, or by imaging the hologram onto the inhomogeneity. The correction is now valid over a wider extent of the image, especially if the inhomogeneity can be treated as planar rather than extending over a volume. Alternatively, a scanning process can be carried out on the object beam falling on the hologram, so that in sequence, each plane wave component assumes the proper angle to counterpropagate along the path for perfect correction, and will form a well-corrected image point. This output spot then falls on a pinhole positioned to separate it from other, imperfectly corrected points. Then, over time, all points of the object will form well-corrected image points, and the entire object will thus be well-imaged. The one way phase conjugation method was first used to correct the spherical aberration of a lens, and the result was quite successful.

Phase conjugation has become an important branch of modern optics. The process is often carried out using photographic materials. More often nowadays, it is carried out using nonlinear crystals. Some of the crystal methods are essentially holography in real time, but others, such as phase conjugation by Brillouin scattering, go beyond holography.

Hyperspectral Imaging

ML Huebschman, RA Schultz, and HR Garner, University of Texas, Dallas, TX, USA

Introduction

Hyperspectral imaging techniques on a microscopic level have paralleled the hyperspectral remote astronomical sensing which has developed over the years. It is especially apparent in remote sensing of our own planet's land masses and atmosphere, such as in the LANDSAT satellite program. In biology, biochemistry, and medicine, hyperspectral imaging and multispectral imaging are often interchanged, although there is a distinct difference in the two techniques.

A multispectral imager produces images of each of a number of discrete but relatively wide spectral bands. Multispectral imagers employ several wide bandpass filters to collect the data for the images. A hyperspectral imager produces images over a contiguous range of spectral bands and, thus, offers the potential for spectroscopic analysis of data. Hyperspectral imagers may use gratings or interferometers to produce the contiguous range of spectral bands to record.

Fluorescent dyes (also referred to as fluorophores or fluorochromes) and recently quantum dots, as markers, are a very powerful tool for analyzing organic tissues for researchers in cytology (study of cell function), cytogenetics (study of the human chromosomes), histology (study of structure and function of tissues), microarray scanning (analysis of concentrations of multiple varied probes), and biological material science. Without the correlation of the spectral and spatial data in biological images, there would be little useful information for the researcher. Therefore, hyperspectral imaging in the biological sciences must combine imaging, spectroscopy, and fluorescent probe techniques. Such imaging requires high spatial resolution to present a true physical picture, and the spectroscopy must also have high spectral resolution in order to determine the quantities of biochemical probes present. The correlation must provide the color-position relation for identification of meaningful information.

This description will begin with an initial review of multispectral imaging to lead into a discussion of hyperspectral imaging. The discussion will examine aspects of hyperspectral imaging based on an interferometric method and on a grating dispersion method similar to the methods in multispectral imaging.

Image Parameters

The analysis of fluorophores involves the excitation of the dye with a shorter wavelength and thus higher energy than the emission spectrum. The use of the appropriate excitation wavelength will yield a maximum emission intensity at a characteristic wavelength. The quality of a fluorescent image generally combines contrast and brightness. Contrast depends on the ratio of emission intensity to that of background light. Consequently, the use of filters to block the excitation wavelength and prevent it from overwhelming the field is critical in providing high contrast for the detection of fluorophore emission. However, the use of narrow filters to restrict the background can severely limit the brightness of the fluorescent image. This is due to the barrier filters allowing only a portion of the actual emission spectrum to pass. Brightness is an intrinsic property of each individual fluorophore, but is also dependent on the ability to illuminate with the peak excitation wavelength for that fluorophore.

The balance between contrast and brightness may be further complicated by applications designed to facilitate the evaluation of multiple fluorophores. The selection of appropriate excitation and emission filters within a single set to allow for the simultaneous viewing of multiple fluorophores can be very inhibiting. Although quad-band beamsplitters are currently available, commercial advances to date have yielded only triple-pass combinations for simultaneous detection, such as one of which permits the simultaneous detection of the widely used fluorophore combination fluorescein-5-isothiocyanate (FITC), Texas Red and 4',6-diamidino-2-phenylindole (DAPI) (e.g., Chroma Technology Corp.).

Although the capture of digital images has propelled this field, efforts to collect multicolored images as digital files also suffer from technical limitations. Color CCD cameras often utilize filters or liquid crystals to segregate the red, green, and blue wavelengths onto the imaging chip. The employment of these cameras is restricted to resolving colors as discriminated by the filters used. For scientific applications, then, the greatest sensitivity and selectivity has been achieved through black and white CCD cameras with optimized filters for a specific application. While this approach is widely used, it suffers from the inherent limits of the spectra of data that can be analyzed since it is defined by the characteristics of the optical filters employed. Thus, the system is restricted to the use of fluorophores that can be effectively resolved from each other by filters, and the filters selected limit the data collected to a portion of the total emission spectrum for any one fluorophore.

Multispectral Imaging

Multispectral imaging systems in biomedical research are composed of a microscope, filters and/or interferometer for spectral selection, a charged coupled device (CCD) camera to record the data, and computer control for acquisition, analysis, and display

Fig. 1 The instruments for multispectral and hyperspectral imaging are similar. (a) Multispectral imagers use interferometers or bandpass filters to collect noncontiguous emission wavelengths. (b) Hyperspectral imagers employ interferometers or gratings to collect a contiguous wavelength band. Computers, microscopes, CCD cameras, and excitation light sources are common to all the techniques. The systems which use filter sets or interferometers use motorized filter placement systems or automated interferometers. The gratings systems employ a motorized stage for the sample movement. Adapted with permission from Schultz RA, Nielsen T, Zavaleta JR, Ruch R, Wyatt R and Garner HR (2001) Hyperspectral imaging: a novel approach for microscopic analysis. *Cytometry* 43: 239–247.

(Fig. 1(a)). The introduction of CCD cameras has offered a means to document results and capture images as digital computer files. This has facilitated the analysis of results with more and more complex probe sets and has allowed the use of more sophisticated computer algorithms for data analysis. The other major component of the multispectral imaging system is a light source to excite the sample's fluorescent dyes whose emissions are selected by filters or an interferometer for recording on the CCD camera.

An example of the use of multispectral imaging is in the identification of the 24 human chromosomes. A scheme was presented for the analysis of human chromosomes by differentially labeling each chromosome with a unique combination of 5 fluorophore-labeled nucleotides (building blocks of DNA and RNA, consisting of a nitrogenous base, a five-carbon sugar, and a phosphate group). These complex probes are simultaneously hybridized to metaphase chromosomes and analyzed to determine which of the

fluorophores are present. Combinations of one, two, or three of the five fluorophores are enough to distinguish a particular chromosome from the others.

An interferometric multispectral system used to perform this type of analysis is the Spectral Karyotyping (chromosome typing) or SKY System (Fig. 1(a)). This technology does not represent hyperspectral imaging, but is presented for comparison. Illumination light passes through a triple band-pass dichroic filter which allows for the simultaneous excitation of all the fluorochromes in, for instance, Speicher's scheme. Modern multi-band pass filters add little to image distortion while effectively blocking unwanted autofluorescence or excitation illumination. The fluorescence emissions from the sample are split into two separate beams by the interferometer. The beams are then recombined with an optical path difference (OPD) between them such that the two beams are no longer in register and interfere with each other. By adjusting the OPD, a particular wavelength band can be selected for, which results in constructive interference and thus can be collected by the CCD camera pixels. After adjusting the OPD to record the 5 dye wavelengths, each pixel's 5 records are then compared to the known probe-labeling scheme to identify the corresponding chromosome material. The image of the metaphase chromosome spread can be karyotyped using specific pseudo-colors for maximal visual discrimination of the chromosomes.

Another nonhyperspectral method is the Multi-Fluorescence *In Situ* Hybridization or M-FISH System. It uses five single-band-pass excitation/emission filter sets where each filter set is specific for one of the five fluorochromes used in the combinatorial labeling process (Fig. 1(a)). Again, five separate exposures are taken (one exposure for each filter set) and combined to create a multicolor image. Most M-FISH systems now have motorized filter set selectors which minimize any image registration shifts that may occur between exposures. For each pixel, the presence/absence of signal from each of the five fluorochromes is assessed and then matched to the probe-coding scheme to determine which chromosome material is present. As with the SKY System, an image of the metaphase spread is converted into a karyotype and specific pseudo-colors are used to maximize visual discrimination of the chromosomes.

Hyperspectral Imaging

As has been stated, the main difference between multi- and hyper-spectral imaging is the collection of a broad contiguous band of wavelengths. The apparatus and methods for hyperspectral imaging are similar to multispectral imaging (Fig. 1). Instead of collecting sections of the emission spectrum using filters or interferometers, hyperspectral imaging collects a continuous emission spectrum by dispersing the wavelength of light using gratings and measuring the wavelength intensity, or by dispersing Fourier components of light using interferometers and measuring interference intensity (Fig. 1(b)). Multispectral images are limited to measuring total intensity within the selected wavelength band. Determining the abundance of more than one dye per pixel is less accurate when only a small segment of each dyes' spectrum is passed by the emission filter. This has not been considered a limitation in the past because most research depended on just identifying the presence and not the abundance of several spectrally broad and overlapping dyes which also occupied relatively large spatial areas. With the advent of smaller and smaller featured microarrays, the desire to use more dyes in identification schemes, and the use of quantum-dot markers which can be used to indicate both genetic makeup and quantity, the limitations of multispectral imaging has led to a move to hyperspectral imaging.

In contrast to the fluorescence multispectral imaging approaches, a hyperspectral image is fully three-dimensional. Every XY spatial pixel of the image has an arbitrarily large number of wavelengths allied with it. An intensity cube of data is collected. Two of the axes of the cube are spatial and one axis is wavelength (see Fig. 2). At each of the 3D points, there is an associated intensity of emitted energy. Therefore, it is a four-dimensional information space. The individual intensity signature of differing emitting bodies can then be separated to give a complete view. Spectral decomposition is a mathematical/algorithmical process by which individual emission spectra of the dyes can be uniquely separated from a composite (full spectral) image by knowing the signature of each dye emission spectra component measured separately. Spectral decomposition may be performed using standard algorithms with codes which are readily available.

Interferometric Hyperspectral Imaging

The system architecture of the interferometric hyperspectral imager resembles that of the SKY System (Fig. 1). But, instead of just sequencing the interferometer to select a set of specific wavelengths to record as in the SKY System, the interferometer in the hyperspectral imager is sequenced through discrete optical path differences to record the intensity at each pixel for each OPD. Fourier spectroscopy techniques are used to transform the OPD intensities at each pixel into the wavelength intensities at each pixel. Each pixel may be thought of as a Fourier spectrometer which is not dependent on any other pixel. Then, spectral decomposition algorithms can be run to determine which dyes are present (see the next section).

Like the multifilter methods, the interferometer approach provides a real two-dimensional image that can be observed, focused, and optimized prior to measurement. But like the filtering methods, the excitation source must be filtered for sufficient contrast to view the fluorescent emissions. Interferometers have high optical throughput, relative to other methods, and can have high and variable spectral resolution. The spectral range can cover from the ultraviolet to the infrared. The high and variable spectral resolution allows the user to trade off sensitivity, spectral resolution, and acquisition time in a way that is not possible with any other technique. And interferometers do not cause polarization of light as a filter may.

Fig. 2 Intensity data cube. In this data cube, each CCD exposure captures a measurement in intensity (number of counts) by wavelength for a small spatial area in Y and ΔX . Many displacements in X with subsequent CCD acquisitions yield a 'cube' of data in X , Y , and λ . The intensity counts may be thought of as another dimension, $I(x,y,\lambda)$. Another form of the data cube is with each CCD acquisition comprising intensity counts for a spatial X and Y area for a small $\Delta\lambda$ and multiple displacements in λ for each acquisition.

However, interferometric instruments are susceptible to image registration and lateral coherence difficulties. They are limited by the extreme precision required of the optical components which results in the continuous need for monitoring and adjustment, since aberrations are not tolerated in interferometric instruments. The throughput is reduced by loss due to the beamsplitter design and from the mirrors. Additionally, the Fourier transform instrument deconvolutes based on a two-step process; the correlation of the light passed by an interferometer followed by an inverse Fourier transform in software.

To mitigate the extreme precision and sensitivity of the most interferometric systems, Sagnac interferometers have been employed because of their common path intrinsic stability. The common path compensates any misalignment, vibration, or temperature affect. The OPD is provided by the Sagnac affect. When the Sagnac interferometer is rotated, the path traveled in one direction will be different from that of the light on the common path in the other direction. Although, this interferometer method is trading one difficulty for another, it is somewhat easier to manage the rotation of a physical system than to maintain the exacting precision of mirror alignments in a standard interferometer.

Spatial Resolution

The spatial resolution of a Sagnac Hyperspectral Imager is set by the size of the pixels of the CCD camera and the microscope system magnification, since the interferometric hyperspectral viewer sees the entire field of view at once. Let the x - and y -dimensions of the CCD pixel be δx and δy , respectively, and the magnification be M , then the spatial resolutions in the x and y directions are $2\delta x/M$ and $2\delta y/M$, respectively. For CCD pixel sizes of 10 microns square, binning together two pixels in the x - and two pixels in the y -direction, and an overall magnification of 60, the x and y resolutions are both 0.66 microns.

Field of View

For N pixel rows and C pixel columns, the field of view will be $N\delta y/M$ and $C\delta x/M$ for the length of the area along the y - and x -axis, respectively. For a CCD array of 1536 columns by 1024 rows, and the parameters above, the field of view is 171 microns by 256 microns, x and y , respectively.

The sensitivity, dynamic range, and spectral response are set by the CCD camera optical components.

Spectral Resolution

Spectral resolution will depend on the ability to vary the OPD and the Fourier transform. While the interferometer is used basically as a filter in the multispectral imager to select a wavelength, in the hyperspectral imager it is used to vary the OPD for all the wavelengths whose energy is integrated at the CCD camera pixels.

The electric field, E , for emissions at one wavelength, λ , or wave number, $k = 1/\lambda$, radial frequency, ω , and amplitude, A , can be written as

$$E(k) = A(k)e^{-i(2\pi kx - \omega t)} \quad (1)$$

and the intensity which is measured is the magnitude squared of the electric field:

$$I = E^* E \quad (2)$$

Emissions from fluorescent sources are usually noncoherent and composed of a range of wavelengths, even with only one dye present. The intensity measured at a pixel is the superposition of many wave numbers. After traveling a certain OPD, L , the intensity integrated over all wave numbers may be written as

$$I_{\text{pxl}}(L) = \frac{1}{2} \left[\int I(k) dk + \int I(k) \cos(2\pi k L) dk \right] \quad (3)$$

or

$$I_{\text{pxl}}(L) = C_0 + C_1 \cdot \text{Re}\{\text{FT}[I(k)]\} \quad (4)$$

where FT stands for Fourier transform.

The inverse transform is

$$\begin{aligned} \int I_{\text{pxl}}(L) e^{-i2\pi k' L} dL &= C_0 \int e^{-i2\pi k' L} dL + C_1 \int \int I(k) e^{-i2\pi k L'} dk \cdot e^{i2\pi k' L} dL \\ \int I_{\text{pxl}}(L) e^{-i2\pi k' L} dL &= C_3 + C_4 I(k) \end{aligned} \quad (5)$$

The integration constant, C_3 , can be ignored for large wave numbers, as in the case of the visible range, since C_3 will be proportional to the inverse of the wave number. The intensity as a function of wave number is then

$$I(k) = C_5 \int I_{\text{pxl}}(L) e^{-i2\pi k L} dL \quad (6)$$

For absolute quantitative measurements, the constant C_5 can be determined by calibration with a known emission. For discrete measurements made by changing the optical path length, then the working formula is

$$I_{\text{pxl}}(k) = \sum_{L_i} I_{\text{pxl}}(L_i) e^{-i2\pi k L_i} \Delta L \quad (7)$$

This is the discrete Fourier transform which must be performed for each pixel to determine the intensity as a function of wavelength. Per the Nyquist sampling tenets:

$$\Delta L = \frac{1}{(N/2)\Delta k} \quad \text{or} \quad \Delta k = \frac{2}{N\Delta L} \quad (8)$$

where Δk is the discrete wave number interval and N the number of different OPDs. Sagnac interferometers can make rotations which give at least a change of $\Delta L = \lambda/4$, so substituting in [Eq. \(8\)](#):

$$\begin{aligned} \Delta k = k_1 - k_0 &= \frac{1}{\lambda_1} - \frac{1}{\lambda_0} = \frac{\Delta \lambda}{\lambda^2 + \lambda \Delta \lambda} = \frac{8}{N\lambda} \\ \frac{\Delta \lambda}{\lambda^2} &\approx \frac{8}{N\lambda} \quad \text{or} \quad \frac{\Delta \lambda}{\lambda} \approx \frac{8}{N} \end{aligned} \quad (9)$$

A 5% resolution in wavelength (or 20 nm at 400 nm) requires $N=160$ and, of course, a 2.5% resolution requires $N=360$. Therefore, about 400 OPD changes and acquisitions of the intensity fringes will give calculated resolutions of less than 10 nm in wavelength.

Analysis of the spectrum based on this resolution can be conducted to determine which dyes are present. Software techniques for displaying data will be described in the next section.

Grating-Dispersion Hyperspectral Imaging

A hyperspectral imaging microscope collects the complete visible emission spectrum from a microscope slide by using a grating spectrometer to provide the wavelength dispersion. This microscope correlates spatial and spectral information with minimal use of optical filters. A hyperspectral microscope system is composed of a standard epi-fluorescence microscope (Olympus IX70) equipped with objectives lens (including $1.25\times$ and $10\times$ Plan Fluorite, $40\times$ Plan Apochromat Dry, and $60\times$, and $100\times$ Plan Apochromat Oil), as well as a set of standard filter cubes (Chroma Technology) to allow for traditional visualization of dyes through the eyepiece. (Prototype typical components are listed in parentheses.) Multiple excitation sources can be utilized including standard 100 W mercury and xenon arc lamps, tungsten brightfield illumination, a 532 nm solid state laser (Brimrose), a helium neon laser (Uniphase), an argon ion laser (Uniphase), and a pulsed-doubled nitrogen dye laser (Laser Science, Inc.) ([Fig. 1\(b\)](#)).

One side port of microscope is optically coupled to a spectrograph (Acton Research SpectraPro[®] 556i). A narrow entrance slit into the spectrograph allows for only one line (ΔX) of the image to be captured at a time. A 50-micron slit permits 80% of maximum throughput for the spectrometer. The spectrograph separates the polychromatic light illuminated from this single line into its light components. Normal operation uses a grating with 50 grooves/mm and a 600 nm-blaze wavelength, which allows

wavelengths of approximately 400–780 nm to be measured. Different spectrograph gratings can be used for special applications from near UV to near IR. The center wavelength and grating can be shifted under computer control. The output of the spectrograph is then captured with an air/liquid-cooled CCD camera (Photometrics-Quantix) and an optional image intensifier (Video Scope International VS4-1845). The camera has a resolution of 1536×1024 pixels with a depth of 12 bits per pixel. The 1536 pixels are aligned in the spatial direction to allow the greatest spatial resolution. During normal operation the wavelength resolution is 'binned' to 128 pixels, sufficient to resolve ~ 8 different spectra in a single excitation scan. Higher resolution can be employed for special applications.

A line of excitation light can be provided by a line generator when laser excitation is used or by a combination of slits and cylindrical lenses when using traditional lamps or burners (mercury or xenon). This line of light illuminates the sample in the same position that maps the resulting emission light through the imaging spectrograph and onto the camera. Some advantages of illumination with a line of light include decreased sample bleaching, reduced background due to scattering, and efficient use of available excitation power. A traditional bandpass, a low-pass dichroic filter, or a linear variable filter (Raynard Corp.) may be employed to select or restrict the excitation wavelength during specific applications.

Linear Variable Filter (LVF)

The linear variable filter (LVF) (Raynard Corporation) can be used to replace the standard excitation filter cube to provide a capability for continuous excitation wavelength band selection. The LVF is $1'' \times 2.25''$ and is coated such that it continuously filters light from ~ 400 nm to ~ 800 nm along its length. Custom filters that span other wavelengths are available. The coating and therefore wavelength is uniform along a short distance, making it an ideal method for selecting an excitation wavelength band to paint across the slide, excite the slide's contents, and map the contents' emission into the slit of the imaging spectrograph. The bandwidth passed is about 21 nm wide. The LVF introduces $\sim 50\%$ attenuation of the intensity.

Spatial Resolution

The spatial resolution of a grating spectrograph Hyperspectral Imager is set by the size of the pixels of the CCD camera in the y -direction and the microscope system magnification. However, differing from the interferometric system, the spatial resolution in the x -direction depends on the spectrometer slit width and the microscope system magnification. As before, let the x - and y -dimensions of the CCD pixel be δx and δy , respectively, and the magnification be M . Let w_s be the slit width of the spectrometer, and note that the slit width is always going to be larger than a few δx . Then the spatial resolution in the y -direction is again $2\delta y/M$, but the spatial resolution in the x -direction is now $2w_s/M$. Again, for CCD pixel sizes of 10 microns square, binning together two pixels in the y -direction, and an overall magnification of 60, the y -resolution is 0.66 microns, as it was for the interferometer method. For a slit width of 50 microns, the x -resolution is 1.67 microns, independent of the number of pixels binned in the x -direction. The control software moves the stage the right number of steps to minimize the overlap or skipped areas. The slit width can be reduced, but at a loss of throughput or increased exposure time. The control software can compensate for different spatial resolution to display the image as 1:1.

Field of View

For N pixel rows (y -dimension) and C pixel columns (x -dimension), the field of view will be $N\delta y/M$ for the length of the area along the y -axis. If the spectrometer slit length is less than the height of the CCD, then the length is just h_s/M , where h_s is the slit length. We orient our CCD array so that the 1536-pixel dimension is along the y -axis. The y -view is thus 256 microns as in the interferometric example. To achieve the same field of view as the Sagnac method imager, we would need to take 103 stage movements and acquisitions. This highlights the difference in the two hyperspectral methods. The grating method collects the complete spectrum on each acquisition with no spectrometer adjustment but needs to step down the slide to produce the full spatial image. The interferometer method collects the complete spatial image on each acquisition with no position adjustment but needs to step the interferometer through a range of optical path differences to acquire multispectral content.

The sensitivity, dynamic range, and spectral response are set by the CCD camera optical components.

Spectral Resolution

Spectral resolution depends on spectrometer instrument function which includes the slit width, the dispersion of the grating, the CCD pixel size, and number of pixels binned together. The dispersion for normal operation was determined to be ~ 40 nm/mm or 0.4 nm/pixel in the 10 micron CCD pixel example. For example, binning of 8 pixels yields a spectral resolution of 3.2 nm at all wavelengths. To achieve this spectral resolution, the interferometer method would require 1000 OPD increments and acquisitions.

Analysis of the spectrum based on this resolution can be conducted to determine which dyes are present. Although the spatial resolutions differ considerably in the two methods, as long as the dye peaks are separated by the spectral resolution spacing, the spectral decomposition algorithms will find all dyes within the spatial resolution area. We have demonstrated that the analysis algorithms can resolve 5 dyes with peaks separated by more than 6 nm in various combinations and known quantity ratios against the dye standards. The program successfully identifies the dyes present with a 91% accuracy in the quantities.

Software

Software (*HyperScope*, a 'C' language program) controls all the hardware components for acquisition. It includes features for analyzing and displaying the resultant $X - Y$ images and spectral information for the grating spectrometer Hyperspectral Imager. During a scan, individual pictures are taken in the $Y - \lambda$ plane, while the stage is incremented in the X -direction. A collection of such $Y - \lambda$ scan files, which can total from 50–1000, is merged to build an image cube (Fig. 2). Another advantage of the single-line acquisition mode is that time-dependent features can be monitored continuously. The software was designed to permit repeated collection of a single line at variable time points. The utility of this feature has been demonstrated by capturing images of fluorescent objects moving through UV-transparent capillaries.

The software was designed to display the resulting $X - Y$ plane extracted in various ways from the image cube. A graph of the emission spectrum for any pixel within that image may be viewed by clicking on any pixel of interest in the $X - Y$ image (Fig. 3(c)). A standard linear curve-fitting algorithm is used to determine the contribution of individual dyes to the measured emission spectrum. The software also features a windowing technique (integration of the emission spectra over a fixed window) which emulates standard filtering. An overlay feature within the software allows the curve fitting results to be displayed in false color and compared by viewing the composite for multiple fluorophores in a single image. Additionally, it permits the contribution of a fluorophore to be emphasized for visualization purposes by either displaying the contribution of a single fluorescent signature in the absence of the others that were present in the image or by scaling individual display intensity values up or down. Overlapping pseudo-colors assigned to represent each fluorophore (either by curve fitting or by windowing) may be displayed as added, averaged, maximum or minimum values. For each new fluorophore–excitation source combination, the characteristic emission spectra is acquired and added to a library of available spectra that can be used as components in the spectral decomposition. This permits the user to introduce new fluorophores at any time. Moreover, background spectra (defined as a region of interest by the user) can be acquired and used as one element of the decomposition. This background component can be turned off in the false color view (as any of the spectral components may be) resulting in enhanced noise reduction and visual contrast improvement.

Description of Acquisition

In order to acquire a full image, a slide is placed on the microstage mover (Ludl Electronics) that allows for precise movement of the sample across the image acquisition plane. The user can position the stage via a joystick or via software to move to pre-determined coordinates. The image is then scanned, with the number of scans being selected at the time of the image acquisition.

Fig. 3 The benefit of spectral imaging is demonstrated in a spatial high-resolution scan of an expression microarray. (a) A portion of the scan of an expression microarray on a microscope slide using the Genepix4000 scanner. It records the intensity emitted by the Cy3 dye when excited with a 532 nm laser. (b) A portion of the scan of the same microarray with the Hyperspectral Imaging Microscope using a 40X objective and Hg excitation lamp. False color is displayed to indicate the intensity variations. (c) A *HyperScope* computer program display of the spectrum recorded when the cursor is placed over one pixel in a scan.

Furthermore, the sample can be scanned at one magnification or resolution and then rescanned at another. Each $Y - \lambda$ image is saved as a single $Y - \lambda$ file for each increment along the sample. Thus, each image file corresponds to the excitation line of light and the emission collection region that maps through the imaging spectrograph to the CCD camera. Saving individual files permits unlimited $Y - \lambda$ image acquisition at the same Y coordinate, valuable for time-dependent studies. This feature also provides some robustness by enabling a partial $X - Y$ image to be displayed should acquisition of one or more Y scans fail for any reason. After acquiring each image, the stage is moved automatically, one or more steps in the X direction, to acquire emissions at the next line and generate the next $Y - \lambda$ file. Therefore, only the fluorescent probes in a line at a single X -location are examined at each acquisition time. Step sizes can be adjusted by the software to give: (i) the best resolution; (ii) the best 1:1 image; (iii) the minimum overlap; or (iv) the fast acquisition time.

After a variable number of rows of associated emission have been captured (typically 50–1000 scans), an image cube is loaded into memory comprising all the $Y - \lambda$ data files. A graph of the spectrum from any pixel (or bin) in the $X - Y$ plane may be displayed in a separate window by clicking on the cube (Fig. 3(c)). A typical acquisition scan of 250 $Y - \lambda$ files, which are used to construct a $250 \times 768 \times 128$ ($\times 12$ bit) image cube, consists of approximately 100 Mb of information.

MicroArray Scanning and Customized Excitation

Another use of this technology is to analyze spotted microarrays. The Hyperspectral Imager has been compared to commercial two-color scanners with comparable sensitivity at approximately 0.5 fluors per square micron (Fig. 3). Increased sensitivity (500–10000 gain) can be provided by using a microchannel plate amplifier (Model VS4-1845, Videoscope International, Ltd.) installed between the CCD camera and the imaging spectrograph.

Since the hyperspectral imaging microscope collects images that reflect only the $Y - \lambda$ plane, it contains the potential to use a single line of light as a source for image illumination. Therefore, lights systems being developed, which are capable of generating a line of light composed of variable or complex wavelengths, could be employed to precisely control excitation. The incorporation of such an excitation source in hyperspectral imaging microscopy could be useful in many clinical and basic research applications.

Imaging Through Scattering Media

AC Boccara, Ecole Supérieure de Physique et Chimie Industrielles and Centre National de la Recherche Scientifique, Paris, France

© 2005 Elsevier Ltd. All rights reserved.

Introduction

We are often faced with the problem of seeing through scattering media such as smoke, fog, clothes, blood, tissues, ceramics, walls, etc. Tremendous effort has been made to introduce techniques which will allow us to overcome the intrinsic difficulty of selecting 'good' photons which are able to provide valuable information on structures which appear fuzzy or, for most of the time, completely hidden.

Although a number of concepts and techniques that we will discuss in this article could be applied to a large number of scattering samples, we will restrict ourselves to biological tissues.

Studying light propagation through biological tissues is becoming more and more popular among physicists, biologists, engineers, and doctors. Indeed this research domain appears to be growing rapidly as seen by the number of published articles, conferences, and international meetings. Optical techniques are attractive and are starting to compete with other well-established techniques (magnetic resonance imaging, X-ray imaging, ultrasonic imaging, positron emission tomography, etc.), because they are nonionizing, nondestructive, they can reach high resolution and are usually much cheaper. Optical techniques reveal an optical contrast which is valuable in providing morphologic as well as functional information.

Most biological tissues are weakly absorbing in the deep red and near infrared region of the spectrum; the main difficulty in performing imaging arises from the high level of scattering. Fig. 1 shows the picture of a small flash light bulb placed in the mouth: it appears fuzzy and red.

In Fig. 2 we consider various photon trajectories between a short pulsed source S and a fast detector D.

Unscattered photons are called 'ballistic' photons, their number decreases exponentially, and they are completely damped after one or two millimeters.

Then there are scattered photons which propagate close to the ballistic trajectory reaching the detector; these are named 'snake-like' photons and can be used for imaging purposes.

Most of the energy which reaches D is related to the scattered photons which may exhibit very long trajectories (typically ~ 10 times the distance S-D).

The description of various experimental methods used to overcome the difficulty introduced by scattering will be associated with the various photon families that we have mentioned: ballistic, snake-like, and scattered photons. We will first give a few orders of magnitude of the parameters which will dictate the way light interacts with the tissues. Let us emphasize that these parameters also carry the information related to the contrast mechanism. The ultimate goal is to realize an 'optical biopsy', noninvasive but as close as possible to the regular biopsy followed by histopathology.

Fig. 1 Biological tissues are highly scattering but the absorption is low in the red (as seen in this digital visible photography) and the near infrared.

Fig. 2 Between an ultrafast light source S and a detector D can be distinguished various classes of photons which can be used for imaging.

Fig. 3 Various sizes of scatterers may be found in cell structures.

Optical Parameters

Scattering Cross-Section

As shown in **Fig. 3**, biological tissues are constituted of structures which exhibit various characteristic scales: from a few nanometers in membranes to about ten micrometers for an entire cell.

As we know from scattering theories these various scales correspond to various scattering properties. For small particles ('small' means much smaller than the optical wavelength λ) we are in the Rayleigh regime which is based on the evaluation of a time-varying dipole induced by a uniform time-varying (at the light frequency scale) electric field. This dipole radiates in the far field and its scattering cross-section, which is the ratio of the scattered power to the incoming irradiance for a sphere of radius r , is given by

$$\sigma = \frac{\langle P \rangle}{I} = \left(\frac{n^2 - 1}{n^2 + 2} \right)^2 \frac{8\pi}{3} r^6 k^4 \quad (1)$$

n being the refractive index of the sphere divided by the index of the surrounding medium and $k = 2\pi/\lambda$. The scattering diagram for such particles is isotropic if we use unpolarized light. This cross-section is much smaller than the 'geometrical' section S of the particle; for instance, if $n = 1.5$, $a = 10$ nm, $\lambda = 0.6$ μm , $\sigma = 1510^{-8}$ μm^2 , which is much smaller than the actual section (3×10^{-4} μm^2).

For larger particles the sphere (or the ellipse) interacting with a plane polarized wave is rather complicated because we are not restricted to the dipolar approximation (uniform field), but induced multipolar moments and their radiating fields have to be taken into account. This theory was proposed by Mie and can be found in optics textbooks. As an example, **Fig. 4** shows the scattering cross-section of a micron-size particle as a function of the wavelength: a number of 'resonances' can be observed.

The scattering diagram is no longer isotropic, it exhibits lobes, and forward scattering is much higher than back-scattering. Scattering is characterized by a scattering coefficient, μ_s , which is the inverse mean free path l_s of photons between scattering events:

$$l_s = 1/\mu_s = \sigma \rho \quad (2)$$

where σ is the scattering cross-section and ρ the number of scatterers by unit volume.

The scattering coefficients μ_s of tissues are found within the range 100–1000 cm^{-1} . After a path length L , the number of ballistic photons will be damped by a factor $\exp(-L/l_s)$, so tissue imaging cannot rely only on ballistic photons as they survive only to a path length larger than about one mm. One needs to consider in more detail the scattering properties of the scatterers.

The dominant sizes of the scatterers in tissue (cells) demand consideration of the scattering in the Mie regime. Such a scattering event does not result in isotropic scattering angles. Instead, the scattering in tissue is biased in the forward direction.

Fig. 4 In the Mie scattering regime resonances are observed when varying the wavelength (here a 1 μm sphere, refractive index: 2).

Anisotropic scattering is quantified in a coefficient, g , which is defined as the mean cosine of the scattering angle θ , $p(\theta)$ being the probability of a particular scattering angle:

$$g \equiv \langle \cos(\theta) \rangle \equiv \frac{\int_0^\pi p(\theta) \cos(\theta) \sin(\theta) d\theta}{\int_0^\pi p(\theta) \sin(\theta) d\theta} \quad (3)$$

For isotropic scattering, $g=0$. For complete forward scattering, $g=1$. In tissues, g varies from 0.7 to 0.95.

Photon migration, especially in the so-called diffusion regime, is often based on isotropic scattering such as for phonons (heat) or charge carriers scattering. For diffusion-like models, it has been shown that one may use an isotropic scattering model with a corrected scattering coefficient, μ'_s , and obtain equivalent results using:

$$\mu'_s = \mu_s(1 - g) \quad (4)$$

One can consider $l'_s = 1/\mu'_s$ as the length over which the incoming photon loses the memory of its initial direction, μ'_s is usually called the transport-corrected scattering coefficient.

Absorption Cross-Section

The absorption coefficient, μ_a (cm^{-1}) represents the inverse mean path length of photons before absorption. $1/\mu_a$ is also the distance in a medium at which intensity is attenuated by a factor of $1/e$ (Beer's Lambert law). Absorption in tissue is strongly wavelength dependent and is due to chromophores and water. Among the chromophores in tissue, the dominant component is the hemoglobin in blood. In the visible range, the blood absorption is relatively high, whereas it is much weaker in the near infrared. Water absorption is low in the visible and NIR region and increases above 1 μm , with tissues turning completely opaque above 2 μm . Thus, for greatest penetration of light in tissue, wavelengths in the 700–1300 nm spectrum are used. This region of the spectrum is called 'the therapeutic window'. Different spectra of chromophores allow one to separate the contribution of varying functional species in tissue such as quantification of oxy- and deoxy-hemoglobin to study tissue oxygenation.

Finally, when light is propagating in scattering media of thickness L , the damping of the incoming energy involves a combination of its absorption and scattering properties, and is given by

$$\exp(-L/a) \quad \text{with} \quad a^2 = 1/3\mu_a(\mu'_s + \mu_a) \quad (5)$$

This formula reflects the fact that the photon's pathlength is increased by scattering, leading to an increase of the damping, which is related to absorption.

These few examples provide a 'static' view of light behavior in scattering media. Studying in a more detailed way, the spatial and temporal distribution of light, is more difficult.

Photon Migration in Scattering Media

Photon migration models have been inspired by other fields, such as astrophysics, soft matter physics, and neutronics, where physical media are random in both space and time. To avoid difficulties linked to the microscopic complexity such investigations rely on a statistical basis.

The most widely used theory is the time-dependent diffusion approximation to the transport equation:

$$\vec{\nabla} \cdot (D \vec{\nabla} \Phi(\vec{r}, t)) - \mu_a \Phi(\vec{r}, t) = \frac{1}{c} \frac{\partial \Phi(\vec{r}, t)}{\partial t} - S(\vec{r}, t) \quad (6)$$

where $\vec{r}$ and t are spatial and temporal coordinates, c is the speed of light in tissue, and D is the diffusion coefficient related to the absorption and scattering coefficients by the formula:

$$D = \frac{1}{3[\mu_a + \mu'_s]} \quad (7)$$

The quantity $\Phi(\vec{r}, t)$ is called the fluence, defined as the power divided by the unit area. This equation does not reflect the scattering angular dependence; the use of μ'_s instead of μ_s ensures that isotropic scattering has been reached. Indeed, for the use of the diffusion theory which implies anisotropic scattering, the diffusion coefficient is expressed in terms of the transport-corrected scattering coefficient; $S(\vec{r}, t)$ is the source term.

The diffusion equation has been solved analytically for different types of measurements such as reflection and transmission modes, assuming that the optical properties remain invariant throughout the tissue. To incorporate the finite boundaries, the method of images has been used.

The diffusion approximation equation in the frequency-domain is the Fourier transform of the time-domain equation. This leads to the equation:

$$\vec{\nabla} \cdot (D \vec{\nabla} \Phi(\vec{r}, \omega)) - \left[\mu_a + \frac{i\omega}{c} \right] \Phi(\vec{r}, \omega) + S(\vec{r}, \omega) = 0 \quad (8)$$

Here the time variable is replaced by the frequency ω which is the modulation angular frequency of the source. In this model, the fluence can be seen as a complex number describing the amplitude and phase of the so-called 'photon density wave' in addition to a DC component:

$$\Phi(\vec{r}, \omega) = \Phi_{AC}(\vec{r}, \omega) + \Phi_{DC}(\vec{r}, 0) = I_{AC} \exp(i\theta) + \Phi_{DC}(\vec{r}, 0) \quad (9)$$

where θ is the phase shift of the diffusing wave whose wavelength is:

$$2\pi \sqrt{\frac{2c}{3\mu'_s \omega}} \quad (10)$$

Although analytical techniques provide a rapid understanding of most phenomena involved in static or dynamic situations, real biological samples are much more complex than homogeneous isotropic media. In these cases, direct and inverse algorithms map the spatially varying optical properties.

Monte Carlo simulations are very popular nowadays; a number of useful programs are available on the websites of various groups. Results may include time or polarization dependence of the photons along their paths.

The other method used in tissue optics is the random walk theory (RWT) on a lattice. RWT models the diffusion-like motion of photons in turbid media in a probabilistic manner. Using RWT, an expression may be derived for the probability of a photon arriving at any point and time given a specific starting point and time.

Imaging in the Ballistic Regime: Taking Advantage of Various Coherence Properties

Shallow Tissue Imaging Through Selection of Ballistic Photons

When imaging thin (less than 2 mm) tissue samples, it is possible to use photons which have not been scattered, called the ballistic photons which can be used to form high-resolution images in the same manner as if no scattering had taken place.

Their number, however, decreases exponentially with propagation distance and this ballistic signal is usually hidden by multiply scattered photons that obscure the image. For relatively shallow tissue depths it is possible to use various spatial filtering techniques to block the multiply scattered photons and there is much current research that aims to extend optical imaging and biopsy to depths of a few mm.

Confocal microscopy rejects much of the scattered light through spatial filtering and has been shown to form 3-D images at tissue depths of up to 200–300 μm , both *in vitro* and *in vivo*, which corresponds to about 50 dB of damping for the ballistic photons.

Two-photon fluorescence microscopy is particularly interesting in this regime since it ensures that all the detected fluorescence photons originate from the desired image plane. This technique also ensures a better penetration (using IR excitation) and a better resolution (nonlinear response) than single photon confocal microscopes.

Imaging to much greater tissue depths does not appear to be practical using optical microscopy and spatial filtering alone and more sophisticated techniques must also be employed to discriminate in favor of the ballistic photons. These techniques exploit either the fact that the ballistic signal photons retain spatial coherence of incident light or the fact that the ballistic photons keep the optical phase memory that multiply diffused photons have lost.

One of the most successful ballistic light-imaging techniques based on the latter filtering approach is optical coherence tomography (OCT) which uses coherence gating using low temporal coherence light and an interferometric detection. Coherent

Fig. 5 The full-field OCT setup based on a Linnik interferometer. The PZT actuator is used to modulate the path difference between the two arms.

detection is used to discriminate against the multiply scattered photons that scatter back into the trajectories of ballistic photons. The ballistic light signal is measured by interference with a reference beam and the resulting pattern is detected with high sensitivity using homodyne or heterodyne detection. By using low coherence length sources and matching the time-of-flight of the reference beam signal to that of the desired ballistic light, OCT can acquire depth-resolved images in scattering media such as biological tissues. For powers in the mW range for tissue irradiation in the infrared, the unscattered ballistic (or more precisely single back scattered) component of the light will be limited by the shot noise detection limit after propagating through approximately 25 scattering mean free paths (MFP) of a scattering medium (or more than 100 dB). This corresponds to a 'typical' tissue thickness of about 1 mm tissue depth for the reflection geometry which is potentially useful for clinical applications such as screening for skin cancer, or for retinal examination.

OCT has proved clinically useful as a means of acquiring depth-resolved images in the eye and is being developed for application in strongly scattering biological tissue. Although the image acquisition requires pixel-by-pixel scanning, the use of new high-power superluminescent diodes in the 100 mW range or of ultrafast lasers to provide high average power, low coherence length radiation (sub-two cycle lasers) has resulted in an *in vivo* OCT system providing real-time imaging.

There are a number of other approaches to coherent imaging, including whole-field 2-D acquisition techniques which remove the need to scan transversely pixel by pixel.

Whole-field imaging using a temporally and spatially incoherent source and a well-balanced interferometric microscope intrinsically provides higher image acquisition rates and can take advantage of inexpensive spatially incoherent, broadband sources such as high-power LEDs, and white light thermal sources.

As an example, Fig. 5 shows Linnik-type white light interferometer with optical path modulation and Fig. 6 an image of an *ex-vivo* rat retina where one can recognize the main feature expected from histology.

Holography, which works in the Fourier space rather than in the object or image space, is also an interferometric technique able to discriminate between ballistic and scattered photons. Since the development of electronic holography, which takes advantage of available arrays of detectors with multimillion pixels, this approach is rapidly growing.

Real-time 3-D imaging systems based on photorefractive holography in multi-quantum-wells devices, which can potentially acquire depth-resolved images at thousands of frames per second, have been demonstrated.

These ballistic light techniques can extend the depth of tissue imaging to the mm range when imaging in reflection. When it is necessary to image through cms, rather than mms of tissue, however, there will be no detectable ballistic light signal and one must extract useful information from the scattered photons.

Imaging in the Snake-Like Regime: Taking Advantage of Time (or Frequency) Gating

The first approach is to use time gating to select the earliest arriving scattered light, which will provide the most useful image information.

For moderate tissue depths one can exploit the fact that biological tissue is highly forward scattering, with most photons being only slightly deviated from their original direction upon each scattering event. After a few cm of tissue, there can be a significant number of photons that have followed reasonably well-defined 'snake-like' paths about the original direction through the tissue, arriving at the detector after the ballistic light but before the fully diffuse photons whose trajectories are effectively randomized.

Fig. 6 OCT rat retinal image: retinal pigmented epithelium. PRL: photoreceptor layer. ONL: outer nuclear layer. OPL: outer plexiform layer. INL: inner nuclear layer. IPL: inner plexiform layer. GCL: ganglion cell layer. NFL: nerve fiber layer.

This early arriving light can be selectively gated using ultrafast lasers and a variety of detectors such as streak cameras, time-gated optical image intensifiers, and time-gated fast photon counting systems, which provide picoseconds time gates.

An alternative, sometimes cheaper, approach to temporal gating is the use of (high) frequency signal discrimination (which is the Fourier transform of the pulse experiment). The periodic solution of the diffusion equation with a periodic source term gives rise to the so-called 'photon density waves'. Such diffusive waves, like thermal waves, are used in the near-field regime (their amplitudes are damped by $\exp(-2\pi)$ after propagating over a single wavelength path) and they can reveal subsurface structures through their refractive and diffusive behavior. Coherence gating and polarization gating can be used when the early arriving light still retains some degree of coherence of the incident light. Indeed polarization discrimination has been used to select those photons which undergo few scattering events and therefore preserve a fraction of their initial polarization state, from the photons which experience multiple scattering resulting in a complete loss of memory of their initial polarization state.

As an example, Fig. 7 shows the image of sub-mm light sources (LEDs) taken through 1 cm of polystyrene solution ($\mu'_s \sim \mu_s \sim 10 \text{ cm}^{-1}$) by selecting photons which kept the memory of their initial circular polarization (here a few less than 1%). One can see the sources quite clearly.

For many important biomedical applications, such as mammography or imaging brain function, it is necessary to penetrate through 5–10 cm of tissue, after which all the detected signal is diffuse. Detecting earlier arriving photons can provide more information but, if the time window is too narrow, the detected signal becomes too weak to use with acceptable data acquisition times.

This problem is, however, being addressed with some success using statistical models of photon transport, with different degrees of approximation ranging from full Monte Carlo simulation of photon propagation to the diffusion equation. The approach is to address the inverse problem, i.e. to measure the scattered light signal as comprehensively as is practical and to calculate what distribution of absorption and scattering properties would have produced the measured signal. This provides a means to quantify the optical properties of biological tissue, averaged over a volume corresponding to a particular distribution of photon paths, and to form relatively low-resolution tomographic images.

Multiplying the number of sources and detectors and correlating the various intensity distributions over the whole structure under examination gives, as expected, better precision in localizing the size and position of the local structure to be identified.

Despite the multiple input and multiple output approaches, real-life situations with the previously mentioned problem of the inhomogeneity of the optical properties of human tissues means that the results are still poor in term of resolution and sub-centimeter structures can hardly be observed in breast imaging, for instance.

One important exception to this limited success in finding precisely the position, the size, and the optical properties of hidden structures is the case of 'activation' studies. This corresponds to a 'differential' situation in which an unknown structure is locally changing with time. Here the goal is not to reach a full description of the unknown structure but only to characterize the local changes induced by the activation.

The main field of application of this approach is certainly in brain activation studies. A matrix of light emitters (usually at two wavelengths which differentiate oxy- and deoxy-hemoglobin, for instance 780 and 840 nm) is coupled to a matrix of light

Fig. 7 Polarization imaging: here the degree of circular polarization is measured in the upper image. The lower image shows the field without polarization filtering.

detectors. The signals are usually balanced and any local change which breaks the symmetry of the scattered photon paths induces a differential signal, easy to detect, because there is no background signal before activation takes place.

Moreover it has been demonstrated that for weak perturbations (weak variations of the optical parameters), the inverse problem can be rigorously solved. This geometrical selection provides a cheap and simple setup with rather spectacular results. Sometimes a modulation is added and the phase shift of the photon density wave is enhanced by the differential approach.

Imaging in the Multiple Scattering Regime: Taking Advantage of all the Photons

Light Only: Transillumination and Fluorescence Imaging

The optical systems used for CW measurements are rather simple and require only the alignment of a number of light sources and detectors. Compared to time-gated techniques due to multiple scattering a much stronger path length distribution is present in the signal and the result is a loss of localization and resolution. In the so-called transillumination geometry, collimated detection is used to isolate multiply scattered photons close to the normal emergence angle.

Direct imaging with the required resolution using CW techniques in very thick tissues, such as breast tissue, has not been established even with sophisticated multi-sources/multi-detectors combinations (typically a few tens of sources and detectors at three different wavelengths).

Despite rapid progress in the modeling of light behavior in scattering media it has not yet been demonstrated that CW imaging can provide images with suitable resolution in thick tissue and time-dependent measurement techniques discussed earlier are dominantly used.

For fluorescence imaging, one has to account for the strong attenuation of light as it passes through tissue. Fluorescent dyes (porphyrin, indo-cyanine, and more recently quantum dots) have been developed that are excited and re-emit in the 'biological window' at near-infrared (NIR) wavelengths, where scattering and absorption coefficients are lower, which is favorable for deep fluorescence imaging. Fluorescent intensity in deep tissues depends on the location, size, concentration, and intrinsic characteristics (e.g., lifetime, quantum efficiency) of the fluorophores, and on the scattering and absorption coefficients of the tissue at both the excitation and emission wavelengths. In order to extract intrinsic characteristics of fluorophores within tissue, it is necessary to describe the statistics of photon path lengths which depend on all these different parameters. The amount of light emitted at the site of the fluorophore is directly proportional to the total amount of light impinging on the fluorophore.

Using fluorescence contrast has the unique feature of carrying two spectroscopic contrasts related to both excitation and fluorescent photons.

The next two techniques take advantage of another way to handle the optical information by coupling optics and acoustics.

Coupling Light and Sound: Acousto-Optic and Photo-Acoustic

Although the two approaches that we will now describe are different in their basic principles as well as in the experimental setups, their names are similar – opto-acoustics (sometimes called photo-acoustics) and acousto-optics.

Opto- (or Photo-)Acoustics

In this technique a pulsed (or modulated) electromagnetic beam irradiates the structure under examination. Despite their tortuous paths (about 10 to 100 cm) photons propagate through the volume in a few nanoseconds. Local absorbing centers then absorb the electromagnetic energy, they experience a fast thermal expansion, and become sources of acoustic waves.

The optical problem of tomographic reconstruction is then transformed into a simpler problem of acoustic reconstruction of source distribution because the speed of the sound is much slower than the speed of the light. More precisely we can compute the signal generated by a short light pulse impinging on a scattering medium which contains an absorber (thickness e) as can be seen on Fig. 8, when $e\mu_a \ll 1$.

The amount of power per unit surface which is deposited in the absorbing slice is $E\mu_a$ (E is the fluence in W/m^2). When the light pulse duration τ is short enough, despite the propagation in the scattering medium ($\tau \ll e/v$ where v is the speed of the sound), we find a variation of the mass by volume unit:

$$\Delta\rho \sim \rho\beta\Delta T \sim \rho \frac{\beta E\mu_a e}{C_v e} \quad (11)$$

The corresponding pressure is:

$$\Delta p = \frac{v^2}{\gamma} \Delta\rho \quad \text{or} \quad \Delta p \sim \rho \frac{v^2 \beta E}{C_p} \mu_a \quad (12)$$

Although this approach is new, compared to the purely optical transillumination approach, it has led to a large number of studies in which time gating brings new information to the accurate determination of the US emitter depth. It has been applied to breast tumor examination to complement standard imaging techniques such as echography and X-ray mammography. Recently this technique has demonstrated submillimeter resolution for *in vivo* blood distribution in rat brain imaging.

Fig. 10 Acousto-optic imaging (lower image) of two absorbing spheres embedded in a scattering medium (upper image shows a section of the gel sample).

Acousto-Optic

Here a DC single frequency laser is used to illuminate the sample. For a typical biological sample a few cm thick the trajectories are distributed between the sample thickness value and more than ten times this value. Due to the good temporal coherence of the source all the scattered photons are likely to interfere when they emerge from the sample volume. These interferences are seen as a speckle field which can be observed at a suitable distance from the sample surface.

As seen in [Fig. 9](#), adding an ultrasonic field will mainly induce a small (smaller than the optical wavelength) displacement of the scatterers (it also induces local variation of the refractive index) which will cause a speckle modulation at the ultrasonic frequency.

If the zone irradiated by the ultrasonic field is optically absorbing, less photons will emerge from this zone than from a nonabsorbing one and thus less modulation will be seen when scanning across the sample volume. This modulation can be detected by selecting a single speckle grain and averaging over a number of uncorrelated speckle distributions to obtain a suitable average value (for instance with latex particles). This is not always possible, in particular because the overall geometry is rather stable in a semisolid tissue. Using a single detector which receives many speckle grains gives less contrast. A multiple detector and a parallel processing of many speckle grains improve greatly the speed and the signal-to-noise ratio: a typical image of absorbing spheres, embedded in a scattering phantom, is shown in [Fig. 10](#).

Conclusion

The complexity associated with multiple scattering in turbid media, such as tissues of the human body, prevents an easy use of light as a routine tool for in-depth examination, whereas superficial examinations have always been sources of diagnostics.

Optical techniques will obviously progress to better characterization of tissues' optical properties, improvement of laser properties and detection techniques, as well as new mathematical approaches of the inverse problem.

We believe that this field of research is still open to new ideas, and new experimental schemes leading to new breakthroughs in the delicate problem of using light in highly scattering media.

Infrared Imaging

K Krapels and RG Driggers, US Army Night Vision and Electronic Sensors Directorate, Fort Belvoir, VA, USA

Published by Elsevier Ltd.

Introduction

All objects above 0 Kelvin emit electromagnetic radiation associated with the thermal activity on the surface of the object. For terrestrial temperatures (around 300 Kelvin), objects emit a good portion of the electromagnetic flux in the infrared part of the electromagnetic spectrum. The visible band spans wavelengths from 0.4 to 0.7 micrometers (infrared engineers typically use micrometer/ μm for wavelength rather than the nanometer or wavenumber more commonly used in other fields). Infrared imaging devices convert energy in the infrared portion of the electromagnetic spectrum into images that can be created by the human eye. The unaided human eye cannot image infrared energy because the lens of the eye is opaque to infrared radiation.

The infrared spectrum begins at the red end of the visible spectrum where the eye can no longer sense energy. It spans from 0.7 μm to 100 μm . The infrared spectrum is, by common convention, broken into five different bands (this may vary according to the application). The bands are typically defined as: near infrared (NIR) from 0.7 to 1.0 μm ; short wavelength infrared (SWIR) from 1.0 to 3.0 μm ; mid-wavelength infrared (MWIR) from 3.0 to 5.0 μm ; long wavelength infrared (LWIR) from 8.0 to 14.0 μm ; and far infrared (FIR) from 14.0 to 100 μm . These bands are depicted graphically in Fig. 1, which shows the atmospheric transmission for a 1-kilometer horizontal ground path for a 'standard' day in the United States. These types of transmission graphs can be tailored for any conditions, using sophisticated atmospheric models such as MODTRAN (from www.ontar.com). Note that there are many atmospheric 'windows', such that an imager designed with such a band selection can see through the atmosphere.

The primary difference between a visible spectrum camera and an infrared imager is the physical phenomenology of the radiation from the scene being imaged. The energy used by a visible camera is predominantly reflected solar, or some other illuminating energy, in the visible spectrum. The energy imaged by infrared imagers (Forward Looking Infrared, commonly known as FLIRs) in the MWIR and LWIR bands, is primarily self-emitted radiation. From Fig. 1, the MWIR band has an atmospheric window in the 3 to 5 μm region and the LWIR band has an atmospheric window in the 8 to 12 μm region. The atmosphere is opaque in the 5 to 8 μm region, so it would be pointless to construct a camera that responds to this waveband.

Figs. 2 and 3 are images that show the difference in the source of the radiation sensed by the two types of cameras. The visible image (Fig. 2) is light that was provided by the Sun, propagated through Earth's atmosphere, reflected off the objects in the scene, traversed through a second atmospheric path to the sensor, and then imaged with a lens and a visible band detector. A key here is that the objects in the scene are represented by their reflectivity characteristics. The image characteristics can also change by any change in atmospheric path or source characteristic change. The atmospheric path characteristics from the Sun to the objects change frequently, because the Sun angle changes throughout the day and also weather and cloud conditions change. The visible imager characterization model is therefore a multipath problem that is extremely difficult.

The LWIR image given in Fig. 3 is obtained primarily by the emission of radiation by objects in the scene. The amount of electromagnetic flux depends on the temperature and emissivity of the objects. A higher temperature and a higher emissivity correspond to a higher flux. The image shown is 'white-hot' or the whiter a point in the image the higher the flux leaving the object. It is interesting to note that trees have a natural self-cooling process since a high temperature can damage foliage. Objects that have absorbed a large amount of solar energy are hot and are emitting large amounts of infrared radiation. This is sometimes called 'solar loading'.

Fig. 1 Visible and infrared spectra.

Fig. 2 Visible image—reflected energy.

Fig. 3 Infrared image—self-emitted energy.

The characteristics of the infrared radiation emitted by an object are described by Planck's black-body law in terms of spectral radiant emittance

$$M_\lambda = \varepsilon(\lambda) \frac{c_1}{\lambda^5 (e^{c_2/\lambda T} - 1)} \text{ W/cm}^2 \mu\text{m} \quad (1)$$

where c_1 and c_2 are constants of $3.7418 \times 10^4 \text{ W } \mu\text{m}^4/\text{cm}^2$ and $1.4388 \times 10^4 \text{ } \mu\text{m K}$. The wavelength, λ , is provided in micrometers and $\varepsilon(\lambda)$ is the emissivity of the surface. A black-body source is defined as an object with an emissivity of 1.0, so it is a perfect emitter. Source emissions of black-bodies at typical terrestrial temperatures are shown in Fig. 4. Often, in modeling, the terrestrial background temperature is assumed to be 300 K. The source emittance curves are shown for other temperatures for comparison purposes. One curve corresponds to an object colder than the background and two curves correspond to temperatures hotter than the background.

Planck's equation describes the spectral shape of the source as a function of wavelength. It is readily apparent that the peak shifts to the left (shorter wavelengths) as the body temperature increases. If the temperature of a black-body is increased to that of

Fig. 4 Planck's blackbody radiation curves for four temperatures from 290 K to 320 K.

Fig. 5 Location of peak of black-body radiation, Wien's Law.

the Sun (5900 Kelvin), the peak of the spectral shape would decrease to 0.55 μm or green light. This peak wavelength is described by Wien's displacement law

$$\lambda_{\text{max}} = 2898/T, \mu\text{m} \quad (2)$$

Fig. 5 shows the peak wavelength as a function of temperature through the longwave region. It is important to note that the difference between the black-body curves is the 'signal' in the infrared bands. For an infrared sensor, if the background is at 300 K and the target is at 302 K, the signal is the difference in flux between these curves. Signals in the infrared ride on very large amounts of background flux. However, in the visible band this is not the case. For example, consider the case of a white target on a black background. The black background is generating no signal, whereas the white target is generating a maximum signal (given that the sensor gain has been adjusted). Dynamic range may be fully utilized in a visible sensor. In the case of an IR sensor, a portion of the dynamic range is used by the large background flux radiated by everything in the scene. This flux never has a small value, hence sensitivity and dynamic range requirements are much more difficult to satisfy in IR sensors than in visible sensors. **Table 1** summarizes this characteristic numerically for the 300 K background and targets shown in **Fig. 4**.

A typical infrared imaging system scenario is depicted in **Fig. 6**. The scene consists of two major components, the target and the background. In an IR scene, the majority of the energy is remitted from the constituents of the scene. This emitted energy is transmitted through the atmosphere to the sensor. As it propagates through the atmosphere it is degraded by absorption and scattering. Obscuration by intervening objects and additional energy emitted by the path also affect the target energy. All of these contributors, which are not the target of interest, essentially reduce one's ability to discriminate the target. So, at the entrance aperture for the sensor, the target signature is reduced from the values observed at the target. Then, the signal is degraded by the optics and scanner (as applicable) of the sensor. The energy is then sampled by the detector array and converted to electrical signals. Various electronics amplify and condition this signal before it is presented to either a display for human interpretation or an algorithm like an automatic target recognizer for machine interpretation. A linear systems approach to modeling allows the components' transfer functions to be treated separately as contributors to the overall system performance. This approach allows for

Table 1 Signal/dynamic range limitation in IR bands

straightforward modifications to a performance model for changes in the sensor or environment when performing trade-off analyses.

History of Infrared Imaging

Night vision systems began to be developed extensively during World War II. Satisfying the requirement to image at night was approached with two different methodologies. The first method was image intensification (I^2). This method involves amplification of any small light that was available and displaying it directly to the eye. Typically I^2 devices are sensitive to visible light and a small portion of the short-wave IR (SWIR, 0.7–3.0 μm) band. They are often classified (along with visible band imagers) as electro-optical (EO) imagers. With an I^2 imager, there must be some source of illumination for them to function well (as little as starlight is sufficient for approx 20/40 acuity with current systems). The second type of night vision device is the infrared or thermal imager (also known as FLIRs). FLIRs are sensitive to the radiation in either the mid-wave IR (MWIR, 3–5 μm) or long-wave IR (LWIR, 8–14 μm) bands.

The first infrared cameras used photographic film that was sensitive to infrared wavelengths. Intelligence and reconnaissance imaging from aircraft drove the infrared system development as a night augmentation to existing visible cameras. These imagers used either continuous moving film or stationary film, like an ordinary camera. A slit aperture was used in the continuous moving film cameras and aircraft motion provided the scan of the scene along the film to build a continuous image. The introduction of television, as electronic imaging in the visible spectrum, led to the development of electronic imagers in the infrared band. Electronic infrared imagers were not restricted to looking down and using aircraft motion for scan, hence these devices came to be known as FLIRs (Forward Looking InfraRed). Today, an electronic infrared imager may be called a FLIR or a thermal imager, with the trend being to use FLIR to describe military applications.

Early FLIRs were often accompanied by illumination devices. They were not very sensitive compared to modern FLIRs so active illumination was necessary. Infrared searchlights or illuminators were used to get higher signal-to-noise ratios. These types of FLIRs are called 'active' IR imagers, while FLIRs that do not use illuminators are 'passive' imagers. Generally, active imagers are used in civil applications and are declining in military use. Broadly, applications for thermal imagers fall into two categories; military and commercial. Table 2 lists some of the purposes and users for modern thermal imagers. The design and performance criteria vary widely for some of the applications.

Types of Infrared Imagers

Infrared imagers are classified by different characteristics: scan type, detector material/cooling requirements, and detector physics. The scan type refers to the method used to construct the electronic image. The camera may use a single detector which is raster scanned over the input scene to build an image. Alternatively, a parallel scan uses a linear array of detectors scanned across a scene

Table 2 Applications of infrared imaging

<i>Category</i>	<i>User</i>	<i>Application</i>
Military	Intelligence analyst	Intelligence surveillance and reconnaissance
	Pilot, driver	Navigation/pilotage
	Gunner, weapons officer	Targeting/fire control

	Doctors	Diagnostic imaging

to build an image. The latest advances in materials have led to staring arrays of detectors. In a staring system, a detector is present in two dimensions to represent each image pixel and no mechanical motion of the focal plane is necessary to construct the image. There are some hybrid FLIR types that combine the different imaging techniques. Usually this combination leads to an improvement in signal-to-noise ratio or to reduce undersampling.

The second classification, by detector material/cooling requirements, usually describes FLIRs built using differing materials. For example, a typical LWIR FLIR material is mercury cadmium telluride (HgCdTe or MCT). In order to achieve high sensitivity, these devices are cooled to decrease dark current. Usually the cooling is based on liquid nitrogen or a cryogenic cooler, and the detectors operate at 77 K. Another common detector material is indium antimonide (InSb), which is used for MWIR FLIRs and is also cooled. A newer class of infrared cameras is not cooled, being referred to as 'uncooled' FLIRs. These uncooled FLIRs are micro-bolometers (resistive elements) or pyrometers (capacitive elements) and have less sensitivity than cooled imagers. Typically, the cooled imagers are comprised of photon detectors while the uncooled imagers are based on thermal detectors, the uncooled FLIRs being used in lower-performance applications.

Infrared Imager Performance

There are three general categories of infrared sensor performance characterizations. The first is sensitivity and the second is resolution. When end-to-end, or human-in-the-loop (HITL), performance is required, the third type of performance characterization describes the visual acuity of an observer through a sensor. The former two are both related to the hardware and software that comprises the system, while the latter includes both the sensor and the observer. Sensitivity is determined through radiometric analysis of the scene/environment and the quantum electronic properties of the detectors. Resolution is determined by analysis of the physical optical properties, the detector array geometry, and other degrading components of the system in much the same manner as complex electronic circuit/signals analysis.

Sensitivity describes how the sensor performs with respect to input signal level. It relates noise characteristics, responsivity of the detector, light gathering of the optics, and the dynamic range/quantization of the sensor. Radiometry describes how much light leaves the object and background and is collected by the detector. Optical design and detector characteristics are of considerable importance in sensor sensitivity analysis. In infrared systems, noise equivalent temperature difference (NETD) is often a first-order description of the system sensitivity. The 3D noise model describes more detailed representations of sensitivity parameters (see Further Reading).

The second type of measure is resolution. Resolution is the ability of the sensor to image small targets and to resolve fine detail in large targets. Modulation transfer function (MTF) is the most widely used resolution descriptor in infrared systems. Alternatively, it may be specified by a number of descriptive metrics such as the optical Rayleigh criterion or the instantaneous field-of-view of the detector. Where these metrics are component-level descriptions, the system MTF is an all-encompassing function that describes the system resolution.

Sensitivity and resolution can be competing system characteristics and they are the most important issues in initial studies for a design. For example, given a fixed sensor aperture diameter, an increase in focal length can provide an increase in resolution, but may decrease sensitivity. Typically, visible band systems have plenty of sensitivity and are resolution-limited, whereas infrared imagers have been more sensitivity-limited. With staring infrared sensors, the sensitivity has seen significant improvements.

Fig. 7 IR imager performance.

Often metrics, such as NETD and MTF, are considered to be separable. However, in an actual sensor, sensitivity and resolution performance are not independent. As a result, minimum resolvable temperature difference (MRT or MRTD) has become the primary performance metric for infrared systems. MRT is a quantitative performance measure in terms of both sensitivity and resolution and a simple MRT curve is shown in Fig. 7. The performance is bounded by the sensor's limits and the observer's limits. The temperature difference (or thermal contrast) required to image smaller details in a scene increases with detail size. The inclusion of observer performance yields a single sensor performance characterization, MRT. It describes sensitivity as a function of resolution, and includes the human visual system.

Many different sensor characteristics may be considered to increase the fidelity of a sensor model. A list of typical infrared imaging system parameters is given in Fig. 8. When considering performance in the system sense, the groupings are often blocks in the system diagram, each with separate transfer functions. This approach works well unless the linear shift invariance assumption is not valid.

General Characteristics of Infrared Imagers

There are a number of imaging characteristics that make infrared systems a little different than conventional visible imaging systems. These include source flux levels, detector charge storage and sensitivity, detector size, diffraction blur, sampling, and uniformity characteristics.

First, we consider the source flux levels. The daytime and night-time flux levels (in photons per second per square centimeter) on Earth in the visible (0.3 to 0.7 μm) is 1.5×10^{17} and around 1×10^{10} , respectively. In the mid-wave (3 to 5 μm), the daytime and night-time flux levels are 4×10^{15} and 2×10^{15} μm where the flux is a combination of emitted and solar reflected flux. In the longwave, the flux is primarily emitted where both day and night yield a 2×10^{17} μm frequency, the AMOP drops rapidly to zero. The effect is to extend the prediction of the MRT beyond the half sample rate and introduce a parameter called minimum temperature difference perceived (MTDP) to replace MRT in the range performance estimate and also in the lab to characterize an undersampled system.

The concept of MTDP follows from observation of standard 4-bar images as the pattern frequency passes the imager half sample rate. The image changes from four bars to three, two, and finally one (can be perceived). The phase of the target image on the detector array may need to be adjusted to observe this progression. The standard MRT measurement requires that all four bars be resolvable by the observer during the measurement process. For use in the lab, the MTDP is defined as the minimum temperature difference at which two, three, or four bars can be resolved in the image of the standard 4-bar test pattern by an observer, with the test pattern positioned at optimum phase. The optimum phase is the phase at which two, three, or four bars are 'best perceived'. TRM3 uses the standard definition of MRT as for adequately sampled imagers. The TRM3 Approach Model is implemented if the imager is considered undersampled as defined when the prefilter MTF at the half-sample frequency is larger than 10%. The MTDP equation is given by

$$\text{MTDP}(f) = \frac{\frac{\pi}{2} \text{SNR}_{\text{th}} \Psi(f)}{\text{AMOP}(f)} \quad (3)$$

where SNR_{th} is a threshold signal-to-noise ratio and Ψ is the total system filtered noise. MTDP is used in the same manner as MRTD in range calculations.

Fig. 8 Factors in infrared sensor modeling.

Fig. 9 Modeling, testing and performance triangle.

Another approach is the triangle orientation discrimination (TOD) threshold. In the TOD, the test pattern is a (nonperiodic) equilateral triangle in four possible orientations (apex up, down, left, or right), and the measurement procedure is a robust 4AFC (four alternative forced-choice) psychophysical procedure. In this procedure, the observer has to indicate which triangle orientation he sees, even if he is not sure. Variation of triangle contrast and/or size leads to a variation in the percentage correct between 25% (complete guess) and 100%, and by interpolation the exact 75% correct threshold can be obtained. A complete TOD curve (comparable to an MRTD curve) is obtained by plotting the contrast thresholds as a function of the reciprocal of the triangle angular size (Fig. 9).

The TOD method has a large number of theoretical and practical advantages: it is suitable for under-sampled and well-sampled electro-optical and optical imaging systems in both the thermal and visual domains, it has a close relationship to real target acquisition, and the observer task is easy. The results are free from observer bias and allow statistical significance tests. The method may be implemented in current MRTD test equipment with little effort, and the TOD curve can be used easily in a target acquisition (TA) model such as ACQUIRE. Two validation studies with real targets show that the TOD curve predicts TA performance for under-sampled and well-sampled imaging systems very well. Currently, a theoretical sensor model to predict the TOD (comparable to NVTherm or TRM3) is under development. The lab measurement and field performance appear sound, but the model is not yet available.

Testing Infrared Imagers: NETD, MTF, and MRTD (Sensitivity, Resolution and Acuity)

In general, imager sensitivity is a measure of the smallest signal that is detectable by a sensor. Sensitivity is determined using the principles of radiometry and the characteristics of the detector. For infrared imaging systems, noise equivalent temperature difference (NETD) is a measure of sensitivity. The system intensity transfer function (SITF) can be used to estimate the NETD, which is the system noise rms voltage over the noise differential output. NETD is the smallest measurable signal produced by a large target (extended source).

Eq. (4) describes NETD as a function of noise voltage and the system intensity transfer function. The measured values are determined from a line of video stripped from the image of a test target, as depicted in Fig. 10. A square test target is placed before a black-body source. The ΔT is the difference between the black-body temperature and the mask. This target is then placed at the focal point of an off-axis parabolic mirror. The mirror serves the purpose of a long optical path length to the target, yet relieves the tester from concerns over atmospheric losses to the temperature difference. The image of the target is shown in Fig. 10(b). The SITF slope for the scan line in Fig. 10(c) is the $\Delta S/\Delta T$ where ΔS is the signal measured for a given ΔT . The N_{rms} is the background signal on the same line.

$$\text{NETD} = \frac{N_{\text{rms}}[\text{volts}]}{\text{SITF_Slope}[\text{volts/K}]} \quad (4)$$

Resolution is a general term that describes the size of resolvable features in an imager's output. With infrared imaging systems, the resolution is described by the system modulation transfer function (MTF). Consider Fig. 11 for the determination of MTF, from either point spread function or edge spread function (psf or esf). In Fig. 11(a), a test target is placed at the focal point of a collimator. The target may be a point, edge, or line as shown in Fig. 11(b). The IR system images this target. The output of a detector scan, or a line of detectors in the staring array case, is taken for analysis, in Fig. 11(c). For the edge spread function, the spatial derivative is taken to get the psf. The Fourier transform is then calculated to give the system MTF as shown in Fig. 11(d). The point spread function is really the impulse response of the system, so a smaller psf is desirable, where a wide MTF is desirable. Such a psf/MTF combination gives a higher resolution.

The MRTD of an infrared system is defined as the differential temperature of a four bar target that makes the target just resolvable by a particular observer. It is a measure of observer visual acuity when a typical observer is using the infrared imager. It results in a descriptor, which is a function not just of a single value. It is a plot of sensitivity as a function of spatial frequency. This parameter can be extended to field performance using Johnson's criteria.

As a laboratory measurement, it uses a 7:1 aspect ratio bar target. The procedure is shown in Fig. 12. A bar target mask, with a black-body illuminator, is placed at the focal plane of a collimator (Fig. 12(a) and 12(b)). The temperature is increased from a small value until the bars are just resolvable to a trained observer (Fig. 12(c)). Then the temperature difference is decreased until the bars are no longer visible. These are averaged for a particular target. The same procedure is performed with a negative contrast bar target. The average of the positive and negative values is the MRT for a particular spatial frequency. These data points are plotted

Fig. 10 NETD measurement.

Fig. 11 MTF measurement.

Fig. 12 MRTD measurement.

and a curve may be fitted to interpolate/extrapolate performance at other than the discrete spatial frequencies of the targets, as in Fig. 12(d).

Summary

We have provided a general description of infrared imaging systems in terms of characteristics, modeling, field performance, and performance measurement. The characteristics of infrared imagers continue to change. Significant changes have occurred in the

past five years, to include the development of higher performance uncooled imagers and ultra-narrow field of view photon systems. Large format detector arrays are commercially available in the mid-wave and are becoming more available in the longwave. Still in the research phase are dual-band focal plane level. At first sight, it appears that the longwave flux characteristics are as good as a daytime visible system; however, there are two other factors limiting performance. First, the energy bandgaps of infrared photons are much smaller than those photons in the visible, so the detectors suffer from higher dark current. The detectors are usually cooled to reduce this effect. Second, the reflected light in the visible is modulated with target and background reflectivities that typically range from 7 to 20%. In the infrared, all terrestrial objects are emitting with an emission temperature of around 300 Kelvin. Typically, a two-degree equivalent black-body difference in photon flux is considered a high contrast target to background flux. The flux difference between two blackbodies of 302 K compared to 300 K can be calculated in a manner similar to that shown in Fig. 4. This is the difference in signal that provides an image, so note the difference in signal compared to the ambient background flux. In the longwave, the signal is three percent of the mean flux and in the mid-wave, it is six percent of the mean flux. This means that there is a large flux pedestal associated imaging in the infrared. Unfortunately, there are two problems accompanying this large pedestal. First, photon noise is the dominant noise and is determined by the mean of the pedestal and is compared to the small signal differences. Second, the charge well storage in infrared detectors is limited to around 10^7 charge carriers. A longwave system in a hot desert background would generate 10^{10} charge carriers in a 33 millisecond integration time. Smaller F-numbers, spectral bandwidths, and integration times are used so that the charge well does not saturate. This results in SNR of 10 to 30 times below the ideal. It has been suggested that some on-chip compression may be a solution to the well pedestal problem. In many scanning FLIR systems, the pedestal is eliminated by AC-coupling the detector signals. Infrared focal plane array (IRFPA) readout circuits have been previously designed and fabricated to perform charge skimming and charge partitioning.

Another major difference in infrared systems, from that of visible systems, is the size of the detector and diffraction blur. For infrared photon detectors, typical sizes range from 25 to 50 μm , where visible systems can be fabricated with 3 μm detectors. Also, the diffraction blur for the longwave is more than ten times larger than the visible blur and mid-wave blur is eight times larger than visible blur. Therefore, the image blur, due to diffraction and detector size, is much larger in an infrared system than a visible system. Also, it is common for infrared staring arrays to be sampling limited where the sample spacing is larger than the diffraction blur and the detector size. Dither and microscanning are frequently used to enhance performance.

Finally, both infrared photon and thermal detectors in staring arrays have responsivities that vary dramatically and it is current practice to correct for the resulting nonuniformity (nonuniformity correction or NUC). The nonuniformity can cause fixed pattern noise in the image that can limit the performance of the system even more than temporal noise (especially in static imaging or stabilized target acquisition imaging).

Modeling Infrared Imagers

Otto Schade Sr. developed the earliest imaging system models and performance measures. His work describing television in the 1950s and 1960s, pioneered the way for the characterizations of imaging sensors used by engineers today. His performance measure for still pictures, moving pictures and television systems was based on an observer resolving a three bar periodic target.

John Johnson developed the technique of relating the acquisition of military targets in the field to laboratory measurements of resolvable bar targets. He divided the discrimination tasks into four categories: detection, orientation, recognition, and identification. This technique was termed an 'equivalent bar pattern approach'. It related performance on a simple test target to performance with complex object targets. Johnson viewed scale models and bar targets in the laboratory against a bland background. The smallest discernible barchart target yielded the maximum resolvable bar pattern frequency. These results, tabulated in Table 3 as cycles across the minimum dimension, were the basis for the discrimination methodology in widespread use today. Note that detection took only one cycle, but as the tasks got more specific or difficult, the requirement went as high as 8 cycles across the target minimum dimension.

Table 3 Johnson's criteria

Target	Resolution per minimum dimension			
	Detection	Orientation	Recognition	Identification
Broadside view				
Truck	0.9	1.25	4.5	8
M-48 Tank	0.75	1.2	3.5	7
Stalin Tank	0.75	1.2	3.5	6
Centurion Tank	0.75	1.2	3.5	6
Half-track	1	1.5	4	5
Jeep	1.2	1.5	4.5	5.5
Command car	1.2	1.5	4.3	5.5
Soldier (standing)	1.5	4.8	3.8	8
105 howitzer	1	1.5	4.8	6
Average	1 ± 0.25	1.4 ± 0.35	4.0 ± 0.8	6.4 ± 1.5

Table 4 Moser's data

Discrimination task	Line pairs/critical dimension
Detect ship	Aperiodic treatment
Classify as combatant	4
Recognize type	10

Recognizing that typical vehicle aspect ratios were somewhat limited, Johnson and Lawson conducted further experiments. Paul Moser conducted some of his own, reanalyzed Johnson and Lawson's, and developed the concept that this task was related to the average or critical dimension instead of the minimum dimension. This led to the conversion of line pairs to resolution elements, introducing the second dimension. Additionally, he performed a similar experiment on marine targets, which is summarized in **Table 4**. Lloyd and Sendall developed the MRT metric, which combines both resolution and sensitivity characteristics. This measurement of MRT is described in detail in a following article, but there is a theoretical model that is used to evaluate new sensor designs and concepts. It relates the minimum temperature difference between bar pairs at which they are just resolvable as a function of spatial frequency. MRT describes the infrared imager sensitivity as a function of resolution. More specifically, MRT is a measure of thermal contrast sensitivity as a function of spatial frequency.

Ratches *et al.* developed the NVL (US Army Night Vision and Electronic Sensors Directorate formerly known as the Night Vision Laboratory) Static Performance Model, which predicted the end-to-end performance. It started with the target signature and carried through to the observer. The MRT, a laboratory measurement or a modeled value, was related to the probabilities of discrimination through the target transfer probability function, cumulative percentages related to Johnson's criteria.

D'Agostino and Webb created the 3D noise model, both spatial and temporal considerations, for analyzing system noise. This technique divided the noise components into manageable and understandable components. It also simplified the integration of these effects into models.

The introduction of focal plane array (FPA) imagers has created a requirement to improve the model performance to account for the difference between scanning arrays and staring arrays. This change has made sampling an important area for improvement. A new model called NVTHERM is a result of the NVESD model improvement effort, which addresses undersampled imaging system performance.

Sensor characterization is seen in three ways: theoretical models, field performance, and laboratory measurements (**Fig. 9**). Theoretical models are developed that describe sensor sensitivity, resolution, and human performance for the purpose of evaluating new conceptual sensors. Acquisition models, and other models, are developed to relate the theoretical models to field performance. This link allows theoretical models to be converted to field performance quantities (e.g., probabilities of detection, recognition, and identification). Field performance is measured in the field so that the theoretical models can be refined and become more accurate with advanced sensor developments. Since field performance activities are so expensive, methods for the direct measurement of sensor performance are developed for the laboratory. Field performance testing of every infrared sensor built, including buy-off, acceptance, and life-cycle testing, is ridiculous and out of the question. Laboratory measurements of sensor performance are developed such that, given these measurements, the field performance of a system can be predicted. Sensor characterization programs require accurate sensor models, field performance estimates with acquisition models, and repeatable laboratory measurements.

There are a few alternatives to the US NVTherm model. One candidate approach to undersampled imager modeling is Germany's TRM3, or the MDTP approach. The impact of undersampling in the image of a 4-bar target can readily be seen by simply observing the change in the image as a function of spatial frequency and phase. The spatial frequency is defined as line pairs per angular extent of the target, and the phase specifies the relative location of the target image to the detector array raster. These effects are obviously not independent of each other, but for each target there can be found an optimal phase where the observer can see the maximum amplitude modulation in the image of the target. MRT measurements in the past have utilized this variation with phase by allowing the observer to optimize the displayed image through target or system line-of-sight changes during the measurement process. For undersampled imagers, TRM3 addresses the problem of the MRT calculation's inability to predict beyond the half sample rate of the sensor, by replacing the MTF in the denominator of the MRT equation with an appropriately scaled term called the average modulation at optimum phase (AMOP). AMOP is the average signal difference in the image of the 4-bar standard pattern, with the test pattern positioned at optimum phase. AMOP oscillates between the pre-sample MTF and the bar modulation. Beyond a frequency of 0.8 times the sample rate or 1.6 times the half sample arrays and quantum well detector systems. These systems will find their place in applications to include both military and commercial sectors.

Interferometric Imaging

DL Marks, University of Illinois at Urbana-Champaign, Urbana, IL, USA

© 2005 Elsevier Ltd. All rights reserved.

Interferometric imaging is image formation by measuring the interference between electromagnetic signals from incoherently emitting or illuminated sources.

Interferometric imaging attempts to improve the resolution of images by interferometrically combining the signals from several apertures. By doing so, a resolution can be achieved that is superior to that achievable through standard image formation by any of the individual apertures. This is especially useful in astronomy, where resolving more distant and smaller stellar objects is always desirable. It is also finding increasing use in microscopy. It has several advantages over conventional noninterferometric imaging methods. The method can combine the light gathered from several imaging instruments to form an image superior to that which can be formed by any one of the instruments. It can also obviate the need to produce a single very large aperture to achieve the equivalent resolution, which in many cases is of impractical size. In addition, because it can produce a phase-resolved measurement, the data can be processed more flexibly to form a computed image estimate. There are also considerable disadvantages to interferometric imaging compared to conventional imaging methods. The amount of signal gathered is far less than could be gathered with an equivalent single aperture. It is difficult to mechanically or feedback stabilize the time delay between two widely separated apertures to obtain an accurate phase measurement. Often only a small bandwidth of the source light can be utilized, further reducing the available signal. The interference component of the combined signal can be very small. Typically an interferometric image must be computed from the data, rather than being directly measured on photographic film or an electronic focal plane array. Even with these disadvantages, interferometric imaging is frequently more feasible than building a single large aperture to achieve the highest available resolution images.

In contrast to interferometric imaging, a standard image forming instrument such as a telescope has a resolution limited by the telescope mirror aperture in the absence of aberrations and atmospheric turbulence. As telescope mirrors become very large, they become bulky, extremely heavy, and difficult to manipulate, as well as deform under their own weight and temperature gradients. However, adaptive optics is being more frequently utilized to dynamically correct for instrument aberrations as well as atmospheric turbulence. The images captured by telescopes are typically intensity-only images, which are amenable to image processing and deconvolution, but nevertheless lack phase information. Interferometric imaging is an alternative, where the resolution of a large aperture can be attained by measuring the interference between individual points of the electromagnetic field within an area equivalent to the large aperture extent. The interferometric combining of light from sub-apertures to achieve the resolution of a larger aperture is called aperture synthesis.

Unlike image formation by a lens, interferometric images are never physically formed. Conventional images are formed when diverging spherical waves emanating from sources are focused by a lens to converging spherical waves on a photographic film or an electronic sensor. In this case, the image information is directly contained in the exposure at each position on the sensor. Interferometric measurements contain the image information as statistical correlations between the electromagnetic fields at pairs of spatial points. The statistical properties of electromagnetic waves are modeled by optical coherence theory. Interferometric imaging works by measuring the statistical correlations between various pairs of points in the electromagnetic field, and then uses optical coherence theory to infer what the image of the source of the radiation is.

The light that emanates from most natural and many artificial sources is incoherent. Incoherent radiation is optical random noise. It is analogous to the sound of static heard on a radio receiving no signal. Because it is random, the fluctuations of the electromagnetic field produced by an incoherent source are completely unrelated to the fluctuations of any other source. The origin of the randomness is usually from microscopic processes such as the thermal motions of electrons or the spontaneous emission of an excited atom. Because these microscopic processes tend to act independently of one another, the light produced by different sources tends to be mutually incoherent. Because incoherent sources do not radiate a deterministic field, the average amount of power they radiate is usually specified rather than the field itself, which is random.

However, as the fields propagate away from their sources, the fields can become partially coherent. To see this, consider the light waves propagating away from a single point-like incoherent source. The field produced at the source point consists of random fluctuations in time, but these fluctuations travel outward in a spherical wave at the speed of light. The fluctuations of the field of any two points an equal distance from the source will be the same, or perfectly correlated, because they arrive from the source at the same time. This is illustrated in [Fig. 1\(a\)](#), where a random wave is emanated from a point incoherent source. Because of the complete correlation, we can say that these two points are fully spatially coherent. So while the source itself produces random noise, the fluctuations of the field at points distant from the source become correlated because they originate from the same source.

Partially coherent waves occur when the measured field contains a superposition of the fields from more than one incoherent source. If there are now two point sources instead of one, each field point in space will receive radiation from both sources. The amount of the contribution from each source to each point in space depends on the distance between the field point and the source. In general, because both sources can be different distances from the two field points, the fluctuations at the field points will not be the same. For example, two field points that are the same distances from both sources will be perfectly correlated, or

Fig. 1 The distance between incoherent sources and two field points determines the coherence between the field points. (a) Because there is only one source, the field everywhere is determined by the radiation of that source. Therefore, the same fluctuations of the wave arrive at two points an equal distance from the source at the same time, and produce identical fields at both points, and so are completely coherent. (b) Two field points are now the same distance from two incoherent sources. Because both sources contribute identical fields to both points (because the fluctuations of the wave from both sources arrive at both points at the same time), the superposition of the fields from both sources at both field points are identical, and so the fields are coherent. (c) Two field points are now near two sources. Because each field point receives radiation mostly from its nearby source and very little from the other source, the fields at each field point are almost completely mutually incoherent.

coherent, because they receive the same combination of fields from both sources. This situation is illustrated in [Fig. 1\(b\)](#). However, if one considers two points that are near both respective sources, the points will usually receive light from the nearby source. Because the sources are incoherent, and each point is mostly receiving radiation from its closer source, these points will be nearly uncorrelated, as shown in [Fig. 1\(c\)](#).

A spatial distribution of incoherent sources radiating various amounts of power will create a pattern of correlations in the field remote from the source. By using interferometry, the correlation between pairs of field points remote from the sources can be measured. The interference between two points in the electromagnetic field is achieved by relaying the two fields (e.g., with mirrors) to a common location that has an equal travel time for the fields from both points, where the fields are superimposed. The power of the superimposed beams is then detected, by a photocathode, for example. If the two signals being combined are incoherent, then no interference will take place, and the total power measured on the photodetector is simply the sum of the power of the two signals. However, if the two signals are partially coherent, there will be a deviation in the measured power from the sum of the power of the two signals. The magnitude of this deviation relative to the power of the constituent signals indicates the degree of partial coherence of the signal.

An interferometer, such as depicted in [Fig. 2](#), gathers the light from two areas of the electromagnetic field remote from an object and combines them together at the same point to form an interferogram. In this example, two telescopes of a known separation gather light from a star. The primary mirror of each telescope is of insufficient size to resolve the star as anything but a point. However, a telescope is used in practice to collect enough light to produce a measurable interference signal. Each telescope primary mirror forms a point image of the star. At the image plane of each telescope a mirror directs the point image to a measurement plane equidistant between the two telescopes. This line that joins the two telescopes is called the baseline, and it is the baseline length rather than the individual telescope mirror size that determines the minimally resolvable size. The image from each telescope is superimposed by mirrors (or perhaps beamsplitters) and imaged onto a focal plane, to get an image similar to that of [Fig. 3](#). If the light arriving from one telescope is blocked, then the image formed looks like an Airy ring pattern formed by an image, a point-like object, which is the incoherent image of [Fig. 3](#). However, when both signals are allowed to interfere, the image will have vertical stripes superimposed on it. If these stripes are very prominent, so that the image is fully darkened inside the stripes, then an image similar to the rightmost image of [Fig. 3](#) is obtained, complete interference is occurring and the two field points at which the telescopes are situated are coherent or completely correlated. If the stripes disappear, then no interference is occurring and the two field points at which the telescopes reside are incoherent. These examples are shown in [Fig. 3](#), with images of two superimposed points with varying degrees of coherence on the top row, and a line plot of the measured field through the center of the images in the bottom row. The degree to which the contrast of the stripes is enhanced by coherence is referred to as the 'modulation' and indicates the degree or magnitude of partial coherence.

In addition to having a degree of coherence, the correlation between two electromagnetic field points also has a relative phase shift. This phase shift is given by the relative position of the interference maxima, as shown in [Fig. 4](#). As the relative phase between the fields collected by the telescopes changes (which is a function of the path length difference between the light arriving at the two telescopes), the peaks of the interferogram between the two telescope images shift position. By observing the depth of the formed

Fig. 2 Two telescopes receive radiation from a stellar object. The light is collimated and directed down the baseline to a point halfway between the telescopes, where the two images are interfered together onto a focal plane.

Fig. 3 The image of two interfering wavefronts from a point object with various states of coherence.

Fig. 4 The image of two interfering wavefronts from a point object with various phase differences between the two wavefronts.

interference fringes and the position of the fringes, both the amplitude and the phase of the correlation between the two field points can be simultaneously measured. The amplitude of the modulation and the phase of the interference are used to compute the complex degree of coherence that is used in the computation of interferometric images.

In practice, the phase of the complex degree of coherence is much more difficult to measure than its magnitude. This is because while the amplitude tends to change very slowly as the positions of the two correlated points change, the phase is sensitive to changes in relative path length on the order of an optical wavelength. Even though a long baseline produces better resolution, the baseline length must be known to a small fraction of a wavelength to obtain a meaningful phase measurement. Minute vibrations

in the positions of the mirrors on the baseline can easily cause fluctuations in the path length greater than a wavelength. This is observed as wild oscillations in the position of the fringes on the image plane. In addition, atmospheric turbulence can also produce large random phase shifts. Achieving a stable phase measurement is one of the most challenging engineering aspects of interferometric imaging.

To model realistic sources, we must determine the coherence produced by sources of a finite size. Finite size incoherent radiators can be regarded as an arrangement of an infinite number of point-like incoherent sources radiating various amounts of power. When an interferogram is made of a field which has two superimposed incoherent sources, the power of the interferograms that each would make alone is added together, rather than the fields of the interferograms. This is because when the fields of the two sources interfere, the phases of both sources are varying randomly over time. The two fields will randomly vary between constructively and destructively interfering with each other. Over a long time, the constructive and destructive interference averages out to no interference. We can then calculate what the interferogram of many incoherent sources combined is by computing the interferogram of a point source and adding the power of many such interferograms together.

To figure out what the power of an interferogram of an arbitrary object is, first consider what the interferogram of a single point source is. Consider a situation depicted in Fig. 5, but with a single point illuminator at the source plane positioned at (x, y, z) with radiant power I . We will have a receiving plane at a distance z from the source plane with two telescopes located symmetrically about the origin at $(\Delta x/2, \Delta y/2, 0)$ and $(-\Delta x/2, -\Delta y/2, 0)$. The fields received at the telescopes from the point will be interfered together at the center of the baseline, which is at the origin. We will assume that the point source produces a narrow band of radiation centered at wavelength λ . The point source produces a spherical wave that is received at both telescopes. The interference power is proportional to the two intensities measured at each telescope with the relative phase at the two telescopes causing constructive or destructive interference:

$$P \propto I_1 + I_2 + 2\sqrt{I_1 I_2} \cos \phi \quad (1)$$

where I_1 and I_2 are the intensities of the field at each telescope, and ϕ is the phase difference between the two fields at each telescope. We will assume that the point (x, y, z) is very far away from the telescopes, and so the intensities at the two telescopes are equal and proportional to the point intensity I , so that $P \propto I(1 + \cos \phi)$. The phase ϕ is given by the difference in distance from the the source point at (x, y, z) to the receivers at $(\Delta x/2, \Delta y/2, 0)$ and $(-\Delta x/2, -\Delta y/2, 0)$. The phase is given by the difference in the Euclidean distances:

$$\phi = \frac{2\pi}{\lambda} (\sqrt{z^2 + (x + \Delta x/2)^2 + (y + \Delta y/2)^2} - \sqrt{z^2 + (x - \Delta x/2)^2 + (y - \Delta y/2)^2}) \approx \frac{2\pi(x\Delta x + y\Delta y)}{z\lambda} \quad (2)$$

where the second term gives the difference in the distance to a first-order approximation in x and y . The interference intensity relation is then $P \propto I(1 + \cos(2\pi(x\Delta x + y\Delta y)/z\lambda))$.

Fig. 5 Diagram of source and telescope plane used for derivation of Van Cittert-Zernike theorem. A source at a distance z from the telescope plane has a power density $I(x, y)$. The telescope plane has two movable apertures symmetric about the origin of the telescope plane separated by $(\Delta x, \Delta y)$. The light from both apertures is directed to the center of the baseline at the origin of the telescope plane, where it is interfered on the sensor.

If the source is now of a finite size, we can regard it as radiating an intensity (power per unit area) $I(x, y)$. To compute the total intensity of the interferogram, we integrate over all the sources in the source plane:

$$P(\Delta x, \Delta y) \propto \int I(x, y) \left(1 + \cos(2\pi(x\Delta x + y\Delta y)/z\lambda) \right) dx dy = \int I(x, y) dx dy + \int I(x, y) \cos(2\pi(x\Delta x + y\Delta y)/z\lambda) dx dy \quad (3)$$

This result can be interpreted as follows. The intensity of the interference when the two telescopes are separated by a distance $(\Delta x, \Delta y)$ is proportional to the real part of the two-dimensional Fourier transform of the intensity distribution $I(x, y)$ evaluated at spatial frequencies $(\Delta x/z\lambda, \Delta y/z\lambda)$, plus a constant intensity. This result, related to the Van Cittert–Zernike theorem, is a commonly used result in interferometric imaging.

By moving the telescopes to various horizontal and vertical separations and measuring the interference intensity, the real part of the Fourier transform of the intensity is inferred. In practice the imaginary part can also be found by varying the baseline optical path length difference by a quarter wavelength. With these samples of the Fourier transform, the inverse Fourier transform computes the image intensity distribution $I(x, y)$. This is how simple computational image formation occurs with interferometric data.

One application of the Van Cittert–Zernike theorem and interferometric imaging is the measurement of the diameter of stars. When observing coherence, the correlations between field points tend to decrease as the separation between the points grows. By observing this decrease of the coherence, the angular size of a star can be measured. This method was pioneered by Albert Michelson in 1890 with the invention of the Michelson Stellar Interferometer. It is needed because the aperture size required to measure the angular diameter of most nearby stars in the Milky Way is larger than the size of most telescope apertures. Stars usually have a circular profile that produces a circularly symmetric pattern of correlations. The coherence between field points as the distance between them is increased does not decrease monotonically, but disappears at certain separations, and has many revivals. The first separation distance at which interference disappears (and the degree of coherence is zero) for a circular profile object is $d_0 = 0.61\lambda/\alpha$, where λ is the wavelength of the light measured from the star, α is the angular diameter (in radians), and d_0 is the first separation from zero at which the interference disappears. In practice, each wavelength produces a null in interference at a different separation, so all but a small bandwidth of the star's light is filtered out before measurement to achieve a suitably strong interference null. For example, for the star Sirius, which has an angular diameter of 0.0068 arc seconds viewed from the Earth, measuring at a wavelength of $\lambda = 500$ nm (blue-green in the visible spectrum), the first separation distance at which no interference will be observed is at 18.5 m. This is larger than the largest available telescope aperture, and therefore an image cannot be directly formed that can resolve the size of Sirius.

Modern examples of stellar interferometry include the European Southern Observatory in Paranal, Chile, the CHARA Array at Mt Wilson, California, USA, and the NASA Jet Propulsion Laboratory Keck Interferometer in Hawaii, USA. The ESO main telescope system is the Very Large Telescope Interferometer (VLTI) consisting of four 8.2 m diameter telescopes as well as several smaller ones that can be moved independently, and will achieve milliarcsecond resolution through the interferometric combination of the telescopes. These telescopes are connected by underground tunnels through which the collected light from each telescope is combined. To measure the phase of the interference, extreme positioning precision is required in the relative delay between the light collected by the telescopes along the baseline, of 50 nm over 120 m, or 1 part in 2400 million, equivalent to 1.6 cm over the circumference of the Earth. Achieving this requires combinations of electronic and mechanical feedback systems with laser stabilized interferometric position measurement. The CHARA array has a very large 330-meter baseline, with 1-meter telescope apertures. The Keck Interferometer consists of two 10 m diameter telescopes with a baseline separation of 85 m. One of the main goals of achieving such high resolution is to be able to observe planets and planet formation around distant stars, to identify possible signs of life in other solar systems.

A similar principle is used for interferometric image formation in radio astronomy. The chief differences are the methods used to collect, detect, and correlate the electromagnetic radiation. Radio astronomical observatories, such as the Very Large Array in New Mexico, USA, and MERLIN at the Jodrell Bank Observatory in Cheshire, UK, use collection dishes and radio antennas to directly measure the electric field, which is not feasible at optical frequencies. These fields are converted to electrical voltages, which can then be directly correlated using electronic mixers, rather than detecting the correlation indirectly through interference. Because the wavelength is much larger, the stability requirements are greatly relaxed. Radio and optical frequency interferometric images are formed in essentially the same way, using the Van Cittert–Zernike theorem.

Interferometric imaging methods have also become of interest for microscopy applications. Aperture synthesis is not needed in microscopy, because the objects of interest are very small and therefore single apertures can be used to achieve diffraction-limited resolution. However, interferometric detection of partially coherent light affords greater flexibility because an image may be computed from the data rather than being directly detected. Typically this is achieved by creating an incoherent hologram of the object, typically through shearing interferometry. For example, by using a Rotational Shearing Interferometer, one can measure an incoherent hologram that can be used to produce a representation of an object with a greatly increased depth-of-field. In addition, direct detection of the partial coherence of sources can allow the methods of computed tomography to be used to produce three-dimensional images of volumes of incoherently emitting objects. Because of the versatility that interferometric detection can provide, interferometric imaging will surely be increasingly used outside of astronomy.

Introduction

The ability to project an image onto a screen in a darkened room has been known since antiquity and Leonardo da Vinci (1515) precisely described principles of the Camera oscura. When one exposes a paper sheet directly to sunlight, it is uniformly lighted. However, if one pierces a little hole through the paper sheet then an image of the sun can be displayed on a screen beyond the hole (Fig. 1). Similarly, the shape of the light spot we can see in a dark room, from the rays passing through a small aperture of a closed shutter, is not that of the aperture. Generally, the spot has a circular shape, as an image of the sun. Actually, it is neither a shadow of the hole nor an image of the sun but a combination of both. Light incident on an aperture contains the entire information about the light distribution of the object, but this information has to be 'deblurred', or decoded. The aperture acts as an elementary spatial 2D-filter that selects and preserves the direction and intensity of light rays coming from each point of the scene. The projection on the screen of each pencil of light passing through the hole is a small light spot, the geometry of which is the same as the aperture, and the intensity is proportional to that of the emitting point. The smaller the hole, the more detail the image exhibits, but with less luminosity. Thus, we must adopt a compromise between the resolution and the illumination of the image.

Now, if the mask has several holes, the amount of light reaching the screen, being proportional to the whole aperture area, is extensively increased. On the other hand, as each hole displays an image on the screen, the overlapping of these multiple images gives a new but blurred image. However, the information exists and we should be able to retrieve it if we know the characteristics of the complex aperture. This is the basic concept of multiplex imaging. The crucial question is: what is a good aperture design and a good way to reconstruct images having high resolution and with high illumination levels? The suitable masks with this aim are named synthetic apertures.

Porta (1589) and Kepler (1611) found the perfect solution, by setting up a lens in front of a large hole. Indeed, one can regard a lens as a wide aperture made of continuously juxtaposed microprisms (Fig. 2). The lens obtains such refractive properties that the image displayed by each of these microprisms is moved toward a center. Moreover, as the angle of the microprisms varies continuously, it focuses on a single point, all the rays coming from a given object point. Thus, the blurring is suppressed and the illumination is increased. The way was opened toward the invention of optical instruments and photography and the 'pinhole' has fallen into oblivion for a long time.

Two new problems awake interest in synthetic apertures, around 1960. First, the domain of imaging has extended out of visible light: infrared and ultraviolet light, γ -rays, X-rays, ultrasound waves, and others. Materials suitable for making lenses or mirrors, operating with such waves, are expensive or often do not exist. For example, most of the transparent materials have a refractive index close to 1 for γ -rays and X-rays. However, some are opaque enough to enable the use of masks.

The second challenge appeared with progress in astronomy. In order to explore the universe more, further from Earth and closer to the Big Bang, astrophysicists needed telescopes providing very high luminosity and high resolution, since distant stars, nebulae, and other galaxies are extremely weak and small luminous objects. This exploration can be achieved by increasing the diameter of the primary mirror of telescopes. Indeed, due to diffraction of light by the pupil of the primary mirror, the theoretical limit of resolution of a telescope (i.e., the smaller distance between two points that one can discriminate), is inversely proportional to the diameter of the mirror. In addition, the illumination is proportional to its area. However, the working of large mirrors is a technical prowess that is very expensive and has high risks. Defect of a fraction of micrometer when polishing the surface can have dramatic consequences, e.g., Hubble. Also, such mirrors, being heavy, can bend out of shape under their own weight. Nevertheless, outstandingly large telescopes have been implemented, based on Adaptive optics: the deformations of the mirror are measured in

Fig. 1 Principle of darkroom.

Fig. 3 Electromagnetic wave propagation.

real time by an interference method and compensated by activating a mosaic of jacks (New Technology Telescope – NTT – European program, 1989). Another way consists in replacing the solid-state mirror by a mosaic of 36 mirrors accurately directed (Keck telescope, USA). However, in either case, the mirror diameter does not exceed 8 to 10 meters. Synthetic apertures could be a solution to that difficulty, as earlier demonstrated by Fizeau (1868) and Michelson (1890).

In the first part of this article, any fundamentals are briefly recalled about properties of light and imaging. The second part describes recent experimental methods and results obtained in synthetic aperture imaging. The last part reports the important programs in progress today relating to stellar interferometry.

Background

Electromagnetic Waves Propagation

Light power, which is involved in image formation, is carried by the electric field of an electromagnetic wave (Fig. 3). The electric field $\vec{E}$ has properties of a vector orthogonal to the direction of propagation $\vec{N}$ of the light ray. It is characterized by its amplitude $\vec{E}_0$, the angular time frequency of vibration ω , and the wavevector $\vec{k}$ which specifies the propagating direction of the ray. Let $P(\vec{d})$ be a current point on a plane wavefront, defined by the position vector $\vec{d}$ from the origin of the reference frame. The electric field propagation of a monochromatic wave is expressed as:

$$\vec{E}(\vec{d}, t) = \vec{E}_0 \exp[i(\vec{k} \cdot \vec{d} - \omega t)] \quad (1)$$

The light power carried by the electromagnetic field is proportional to $I = \|\vec{E}_0\|^2 = \vec{E} \cdot \vec{E}^*$ where $\vec{E}^*$ is the complex conjugate of $\vec{E}$. The time frequency $\nu = \omega/2\pi$, or the wavelength $\lambda = c/\nu$, where c is the electromagnetic wave celerity, characterize the hue of the

Fig. 4 Spatially coherent light.

Fig. 5 Spatially incoherent light.

light. The wavevector $\vec{k} = \vec{N}\omega/c$ where $||\vec{N}|| = 1$ is an angular space frequency vector, as $\vec{n} = \vec{N}/\lambda = \vec{N}v/c$ is a space frequency vector. We have $\vec{k} = 2\pi\vec{n}$. As λ is a constant for a given monochromatic light, $\vec{n}$ defines the direction of propagation of a ray.

Spatially Coherent Light

Consider a very small source stated as the point source S_1 , emitting uniform lightwaves in any direction (Fig. 4). The wave reaching a farfield point P , from S_1 , propagates along a direction defined by the wavevector $\vec{k}_1$. The vectors $\vec{k}_1$ and $\vec{d}_1 = S_1P$ are collinear. Another point source, S_2 is characterized from P by the wavevector $\vec{k}_2$ such that $\vec{k}_2$ and $\vec{d}_2 = S_2P$ are collinear. When the distances d_1 and d_2 are close to each other, the amplitudes $\vec{E}_{01}$ and $\vec{E}_{02}$ of the waves at P are proportional to those of the corresponding emitting sources, S_1 and S_2 . According to the principle of superposition, the resulting field at the point P , $\vec{E} = \vec{E}_1 + \vec{E}_2$ and the instant wavevector $\vec{k}$ are unique vectors.

If S_1 and S_2 are two synchronous sources, the amplitude $\vec{E}_0$ of $\vec{E}$ and the wavevector $\vec{k}$ are constant versus time at any point P . This is still the case when an extended object is made of an arrangement of synchronous points. That situation defines a spatially coherent object. Thus, one cannot recover multiple data about the object's distribution, from the field framework at a single point P , since the relationship between the two is multi-unequivocal. Nevertheless, due to diffraction, one can retrieve them by knowing the complex amplitude distribution of light on a set of wavevectors available over an extensive area of a screen. Let $\vec{E}_0(\vec{r})$ be the amplitude of the electric field at the object point $M(\vec{r})$ and let $\vec{E}_0(\vec{n})$ be the one diffracted by the object to farfield toward the direction corresponding to the space frequency $\vec{n}$. Fourier transforms give the connection between $\vec{E}_0(\vec{r})$ and $\vec{E}_0(\vec{n})$:

$$\left\{ \begin{array}{l} \vec{E}_0(\vec{n}) = \int \vec{E}_0(\vec{r}) \exp[i2\pi\vec{n} \cdot \vec{r}] d\vec{r}, \\ \vec{E}_0(\vec{r}) = \int \vec{E}_0(\vec{n}) \exp[-i2\pi\vec{n} \cdot \vec{r}] d\vec{n}. \end{array} \right\} \quad (2)$$

This is the situation encountered when an object is illuminated by a laser or by a point source such as a single star.

Spatially Incoherent Light

When the point sources S_1 and S_2 are independent – spatially incoherent – both wavevectors $\vec{k}_1$ and $\vec{k}_2$ coexist at the point P , each characterizing the angular position of S_1 and S_2 (Fig. 5). If S_1 and S_2 are part of an extended intensity distribution $I_0(\vec{r})$ fans of wavevectors and fields are mixed at P , each coming from an independent point source S . Together, they carry the whole data on the object distribution. Those data are partially uncorrelated at any two points P and P' on a screen, related to the different optical paths from any point S to P and P' and to the finite time of coherence of light. The correlation between data available to farfield in two directions $\vec{n}$ and $\vec{n}'$ from the object, is given by the mutual intensity function, $\Gamma(\delta\vec{n}) = \int \vec{E}(\vec{n}) \cdot \vec{E}^*(\vec{n} + \delta\vec{n}) d\vec{n}$ where $\delta\vec{n} = \vec{n}' - \vec{n}$. Fourier transforms give the relation between $I_0(\vec{r})$ and $\Gamma(\delta\vec{n})$:

$$\begin{cases} \Gamma(\delta\vec{n}) = \int I(\vec{r}) \exp[i2\pi\delta\vec{n} \cdot \vec{r}] d\vec{r}, \\ I(\vec{r}) = \int \Gamma(\delta\vec{n}) \exp[-i2\pi\delta\vec{n} \cdot \vec{r}] d\delta\vec{n} \end{cases} \quad (3)$$

Therefore, by drawing a map of $\Gamma(\delta\vec{n})$ one can recover the object distribution $I_0(\vec{r})$ by a Fourier transformation. Most of time, one uses the spatial degree of coherence function, $\gamma(\delta\vec{n}) = \Gamma(\delta\vec{n})/\Gamma(\vec{0})$. When the object illuminates a screen, at a large distance d , the degree of coherence of light between two points P and P' on the screen is $\gamma(\delta\vec{p}/\lambda d)$ with $\delta\vec{p} = \vec{PP'}$. The 2D extension of $\gamma(\delta\vec{p}/\lambda d)$ defines the area of coherence of light on the screen. The width of the area of coherence, $\Delta\rho$, and that of the object distribution, Δr , are inversely proportional:

$$\Delta\rho \cdot \Delta r \sim \lambda d \quad (4)$$

If a mask perforated by two pinholes, separated by a distance $\delta\vec{p}$ replaces the screen, one can observe Young fringes of interference beyond the mask, the visibility of them being precisely $\gamma(\delta\vec{p}/\lambda d)$. Therefore, one can build a map of $\gamma(\delta\vec{p}/\lambda d)$ versus $\delta\vec{p}$ from a set of 2D measurements of visibilities of fringes, then reconstruct the object distribution by a Fourier transformation.

Notice that the entire data of the object distribution is available from a single coherence area. That is, a pinhole covering exactly one area of coherence would select the entire available data from the object and would display to farfield the most accurate image possible. Generally, such a pinhole is so small that practically no light passes through it. However, we can regard each area of coherence as an independent channel of information. Then an imaging device based on a juxtaposition of such redundant channels can be considered as a multiplex imaging device.

Self-luminous objects such as extended or double stars, and artificial thermic sources are spatially incoherent sources.

Multiplex Imaging

Methods of multiplex – or lensless – imaging are performed either with coherent or incoherent light. The very different properties of the two types of light leads to completely different methods, even if all are related to holography. Holography with coherent light is an interference method for local recording of both the direction and modulus of the wavevectors and the amplitude of the field contained in many juxtaposed grains of speckle, scattered by the object. Each grain is an independent channel of imaging.

Synthetic Apertures with Spatially Incoherent Objects

As interferences are impossible by this method with incoherent light, we must improve other methods of imaging. Synthetic aperture is a concept consisting of using a redundant multichannel system to increase the luminosity of images without loss of resolution. The basic principle is that of a multiple holes darkroom. The processing is in two steps: recording and reading the image. The recording step consists in illuminating a photosensitive receptor with the object through a mask (Fig. 6). Generally, the receptor is a photographic plate. Obviously, the light distribution on the plate is blurred. Indeed, any elementary transparencies on the mask project on the receptor inverted images of the object located the shadow of the mask. Such a distribution is expressed by a convolution. Let $O(x,y)$ be the conical projection of the object on the receptor and $Z(x,y)$ that of the mask. The shadows distribution on the receptor is (the variable being normalized):

$$I'(x',y') = Z(x,y) * O(x,y) = \int Z(x,y) O(x' - x, y' - y) dx dy \quad (5)$$

The reading step is a decorrelation processing from the recorded intensity (Fig. 7). It consists in achieving a new correlation of I' with an arbitrary function T :

$$I''(x,y) = T(x,y) * [Z(x,y) * O(x,y)] = [T(x,y) * Z(x,y)] * O(x,y) \quad (6)$$

Fig. 6 Principle of synthetic aperture: recording.

Fig. 7 Synthetic aperture: reading.

Fig. 8 Properties of FZP.

Fig. 9 Recording and analogical reading with a FZP.

$R[x, y] = [T(x, y) * Z(x, y)]$ is the system point spread function (SPSF) of the processing. It expresses the image distribution of a single-point. The perfect image is obtained when $R(x, y)$ is a 2D Dirac – or delta– distribution, $\delta(x, y)$:

$$R(x, y) = \delta(x, y), \text{ as } \int \delta(x, y) O(x' - x, y' - y) dx dy = O(x', y') \quad (7)$$

Fresnel zone plates

First Mertz and Young used Fresnel zone plate (FZP) as a synthetic aperture for X-ray imaging purposes. FZPs are made of alternate transparent and opaque concentric crowns of equal area. The radius of the n th circle is $r_1 \sqrt{n}$, r_1 being the smallest. When illuminated by a cylindrical light beam, the FZP is a multiple foci diffractive lens (Fig. 8).

The reading step is either analogical or numerical. Through the analogical method, we consider the recorded plate as a pseudohologram (Fig. 9). When the 'shadowgram' is lighted with a parallel beam of laser light, the FZPs recorded around each point concentrates the light on its foci. Then an image of the object is reconstructed on the focal planes; a method that is simple and elegant. Nevertheless, the processing is not linear since we record an intensity distribution at the recording step, while the reading step by diffraction involves amplitude. Moreover, the S/N ratio decreases as the amount of data increases, recorded on the photographic plate because of its finite dynamic.

Mertz and Young had the idea of using a second FZP to perform the deconvolution processing by optical methods. In this case, the SPSF, $R(x, y)$, is the autocorrelation function of the FZP transparency (Fig. 10). It presents a narrow central peak, emerging from a pyramidal ground (Fig. 11). The optical setup is the same as the recording step. The FZP scale factor only must be adjusted to compensate for the magnification ratio generated by the conical projection at the recording step.

Fig. 10 Optical decorrelation.

Fig. 11 System point spread function with a Fresnel zone plate.

In either digital or analogical deconvolution, the image reconstructed is accurate, with good sharpness, if the number of zones is sufficient. Ceglio *et al.* obtained relevant images of 8 μm targets with FZP having 100 zones. Nevertheless, the multiple foci of FZP induces decreasing of the S/N ratio which is an important limitation. Besides, we pointed out above that the larger the object, the more the decrease in the S/N ratio.

Random and uniformly redundant arrays

Dicke and Ables substituted a random array to the FZP. The mask is made of randomly distributed holes and the expected advantage is doubled. First, one can reduce the transparent area of the mask by less than 50% in order to increase the S/N ratio when the object is wide. Second, the autocorrelation function of such an array is theoretically a Dirac distribution when its width is infinite. Thus, one can hope to narrow the system point response. However, when the width is finite, the pyramidal ground of the point response mentioned above is present and the advantage is not clearly demonstrated. In order to correct this effect, Chris Brown used a 'mismatched' function, for the postprocessing deconvolution. This function is calculated, first by achieving the complement of the recording mask function, then subtracting from it. Thus, the 1 transparencies result in $+1$ while the 0 transparencies are changed by -1 . Brown shows images digitally reconstructed of X-ray sources, 30 sec. of arc wide. Fenimore and Cannon conceived a uniformly redundant array. The center random motif of the mask is half replicated on each side with only the center area being used for the recording step. The deconvolution is calculated by taking into account the whole area in a mismatched way. The result is an exact delta function. The authors show images of 200 μm -wide microspheres with a similar resolution but a signal 7100 times stronger than with a comparable pinhole camera.

Theta Rotating Interferometer

The theta shearing interferometer enables us to record complete data from the Fourier transform of a spatially incoherent object (Fig. 12). The source can be any natural one, but monochromatic. This is easily practicable using a good filter or monochromator.

The device is based on a Michelson interferometer, the plane mirrors being replaced by two roof prisms. One of the roof prisms is fixed so the other can rotate around the axis of the interferometer. As a result, we have two images of the object. Let θ be the angle between the two edges of the prisms. The angle between the images is 2θ . Since the original object is noncoherent, and two homologous points being mutually coherent, the light they emit interferes, resulting in fringes.

The intensity, space frequency, and direction of the fringes characterize the intensity and the position of the point source. One shows that the farfield visibility distribution of fringes $V(\delta\vec{n})$ and the object distribution $O(\vec{r})$ are related by Fourier transforms:

$$\begin{cases} V(\delta\vec{n}) = \int O(\vec{r}) \exp \left[i 2\pi \frac{\delta\vec{n} \cdot \vec{r}}{2\sin\theta} \right] \frac{d\vec{r}}{2\sin\theta}, \\ O(\vec{r}) = \int V(\delta\vec{n}) \exp \left[-i 2\pi \frac{\delta\vec{n} \cdot \vec{r}}{2\sin\theta} \right] d\delta\vec{n} \end{cases} \quad (8)$$

Then, one can see that the visibility of the interference pattern is an image of the degree of coherence $\gamma(\delta\vec{n})$ with a scale factor $1/2 \sin \theta$.

Such a pattern recorded on a photographic plate is a Fourier hologram of the noncoherent object. An image can be reconstructed by diffraction at infinity or near a focus (see Fig. 13, examples performed in 1972 by the author). The technique was successfully applied to the determination of the modulation transfer function of optical systems. C Roddier and F Roddier applied

Fig. 12 Theta shearing interferometer.

Fig. 13 Incoherent light holograms.

the method to astronomy. For instance, they examined Alpha Orionis and discovered the evolution of its dust envelope and the possible existence of a companion.

High Resolution Imaging in Astronomy

In astronomy, the limit of resolution depends chiefly on two factors. The first is a technical one. Adaptive optics and very large telescopes (VLT) brought spectacular progress to clarity and resolution of telescopes. The 8.2 m VLT of Kueyen set up in 1989, shows images easily resolved of HIC 69495 Centauri, separated by 0.12 sec. of arc. Nevertheless, working of large mirrors for telescopes reaches its limits. Therefore, their clarity remains too weak. On the other hand, atmospheric turbulences make the refractive index of air unstable and the position of the images in the focal plane of telescopes unsettled. Thus, the point response is a granular spot named 'speckle'. Short exposure times relieve that inconvenience, but they prohibit the observation of weak stars. In 1970, Labeyrie proposed a method of speckle interferometry consisting of a statistical analysis of a set of speckles. The result is a display of a diffraction-limited image. He resolved many tens of single and double stars. Only Hubble, above the atmosphere, is able to do it by direct imaging. However, the primary mirror of Hubble being only 2.40 m wide, has clarity much lower. Stellar interferometry is a very promising alternative solution.

Principles of Stellar Interferometry

Stellar interferometry is based on Eq. (3). The light emitted by double or wide stars is noncoherent, so that one can access an image of them through 2D measurements of the degree of coherence of light. We showed above that one could achieve this by using interference devices such as Young holes. Eq. (3) shows that if we measure the visibility of Young fringes at increasing distances $\delta\rho$ between the pinholes, the distance $\Delta\rho$ from which the visibility is zero gives the angular width of the star, $\Delta\alpha$, under the formula:

$$\Delta\rho \cdot \Delta\alpha \sim \lambda \quad (9)$$

where $\Delta\alpha = \Delta r/d$. In the case of a double star, the visibility varies periodically versus $\delta\rho$ when the pinholes are aligned along the axis of two stars. Let $\Delta\alpha$ be the angular distance between the stars: the smallest distance $\Delta\rho$ for which the visibility is zero is given by:

$$\Delta\rho \cdot \Delta\alpha = \lambda/2 \quad (10)$$

The larger the uttermost distance between the holes, the more the limit of resolution of the processing is potentially sharp.

In order to exploit this idea, Stephan placed and rotated a mask with two holes in front of the objective of a refractive telescope. He established that the diameter of the stars he observed was much less than 0.16 sec. of arc. Then, Michelson built up, on top of a

Fig. 14 Stellar interferometer of Michelson.

Fig. 15 The two telescopes interferometer of Labeyrie.

30 cm refractive telescope, a stellar interferometer consisting of two arms catching the light at 7 m of distance from each other (Fig. 14). He measured correctly the diameter of the satellites of Jupiter. Hale carried the distance of the base up to 15 m in 1920.

The Two Telescopes Interferometer of Labeyrie

In 1975, Labeyrie improved the idea by setting up two separate 25 cm diameter Cassegrain-coudé telescopes on a 12 m baseline, oriented north–south (Fig. 15). The setting and mechanical stability of the device are extremely sensitive. The tolerances do not exceed any μm . A mobile table near the common focal plane of the two telescopes compensates for the optical path differences due to stars tracking. In spite of the acute difficulties, he succeeded in observing fringes on Vega. He obtained a resolution of 0.01 sec. of arc versus 0.5 sec. with a single 25 cm telescope. Later, one telescope was rendered mobile bringing the base width variable between 4 and 67 m. The resolution reaches up to 0.00015 sec. of arc. Note that the rotation of Earth also enables east–west analysis with resolution of 0.005 sec., and today, the 25 cm telescopes are replaced by 1.5 m ones.

The Very Large Telescope Interferometer (VLTi)

The two telescopes interferometer of Labeyrie is a first step toward a very ambitious project: the telescope at synthetic aperture and very large base. Proofs of reliability of such a principle was already given by the very large array (VLA) experimented in radio astronomy. Labeyrie with Lena, and the team of the ESO (Ecole Supérieure d', Paris), imagined a very large telescope interferometer (VLTi) made of 6 telescopes of 2 m, in a 2D structure on a base of 100 m. The European VLTi was built at Cerro Paranal. It is made of four 8.2 m telescopes corrected in real time by adaptive optics (NTT technology) and three 1.8 m telescopes. The

fourth 8.2 m telescope was put in service in 2001. Some days, each of the 8.2 m telescopes used separately gives a resolution close to that of Hubble. However, the clarity is much better because of the larger primary mirror diameter (8.2 m against 2.4 m). In May 2003, the team of J-G Cuby observed a galaxy the farthest away ever seen, only 900 millions years old since the Big Bang. Obviously, a drastic gain of resolution (by a factor 10) is expected from the interference configuration.

Nomenclature

μ_a [cm^{-1}] Absorption coefficient
Alternating part of PDW, alternating current (ac)
 g_1 Average cosine of the scattering angle
 ω [s^{-1}] Circular modulation frequency
Computed tomography (CT)
 $\{\Delta\mu_a(\mathbf{r}), \Delta\mu'_s(\mathbf{r})\} = \{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\} - \{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\}_e$
 $[\text{cm}^{-1}]$ Difference between the estimate and actual optical properties
 $D = v/(3\mu_a + 3\mu'_s)$ [cm^2/s] Diffusion coefficient
Diffusion equation (DE)
 $S(\mathbf{r}, \hat{\Omega}, t)$ [$\text{W cm}^{-3} \text{steradian}^{-1}$] Distribution of light source power
 ∇ [cm^{-1}] Divergence operator
 $\{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\}_e$ [cm^{-1}] Estimate of optical properties
 F General nonlinear operator
 J Jacobian
 Δ [cm^{-2}] Laplace operator
Magnetic resonance imaging (MRI)
 $\{\mu_a^m, \mu_s^m\}$ [cm^{-1}] Measured bulk optical properties (absorption and reduced scattering coefficients)
 ν [s^{-1}] Modulation frequency
Non-alternating part of PDW, direct current (dc)

$\{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\}$ [cm^{-1}] Optical properties of the medium (absorption and reduced scattering coefficients) as functions of spatial coordinate
 $\phi(\mathbf{r})$ Phase as a function of source–detector distance
 $f(\hat{\Omega}, \hat{\Omega}')$ Phase function
 $U(\mathbf{r}, t)$ [J cm^{-3}] Photon density
Photon density wave imaging (PDWI)
Photon density wave (PDW)
 l [cm] Photon mean free path
 $L(\mathbf{r}, \hat{\Omega}, t)$ [$\text{W cm}^{-2} \text{steradian}^{-1}$] Radiance
 $\Phi(\mathbf{r}, t)$ [W cm^{-2}] Radiation fluence
 $J(\mathbf{r}, t)$ [W cm^{-2}] Radiation flux
 μ'_s [cm^{-1}] Reduced scattering coefficient
 μ_s [cm^{-1}] Scattering coefficient
 G Set of measured values (ac, dc, and phase)
 G_e Set of predicted values (ac, dc, and phase)
 $Q(\mathbf{r}, t)$ [$\text{J cm}^{-3} \text{s}^{-1}$] Source term
 r [cm] Source–detector distance
 $\mathbf{r}$ [cm] Spatial coordinate
 v [cm/s] Speed of light in medium
 $Y_{nm}(\hat{\Omega})$ Spherical harmonics
Transport equation (TE)
 $h(\mathbf{r})$ Weight function
 $x = \omega/(\nu\mu_a)$

Photon density wave imaging (PDWI) employs diffused light, usually in the near-infrared band, for imaging inhomogeneous structures in a highly scattering medium. The other names for PDWI are diffuse optical tomography and photon migration imaging. The term photon density wave (PDW) refers to the wave of light density spreading in the highly scattering medium from the source whose power changes in time. Therefore, rigorously speaking, photon density wave imaging uses intensity-modulated light sources, such as pulsed lasers, or sources whose power is harmonically modulated. However, many applications employ steady-state light sources. Most applications of PDWI are in the field of imaging of biological tissues, including medicine and cognitive neuroscience.

As in the other imaging methods, such as x-ray, computed tomography (CT) or ultrasound imaging, the problem of PDWI consists in the reconstruction of the internal structure of the medium from the measurements made outside the medium (on its surface). In the case of PDWI the internal structure of the medium is represented by the spatial distribution of its optical properties. The reconstruction procedure is essentially an iterative mathematical algorithm, which includes the modeling of the light propagation inside the medium assuming a certain distribution of the optical properties, and the correction of this distribution to match the model prediction with the actual measurement. The modeling part of the imaging problem is usually referred to as the forward problem, and the correction procedure is known as an inverse problem.

Forward Problem: Photon Density Waves

Unlike optically transparent media, in a highly scattering medium the coherence of light from the coherent source very rapidly decays with distance. This happens due to the interference of many randomly and multiply scattered light waves at every point of the medium that is distanced from the source much farther than the photon mean free path l , which is the mean distance at which a light wave undergoes a single scattering event. For biological tissues, where light scattering occurs on cell membranes and other heterogeneities of the index of refraction, l is typically about 1 mm. Although high scattering eliminates the coherence of the electromagnetic waves at the short time intervals corresponding to oscillation at optical frequencies ($\sim 10^{-15}$ s), in the case of an intensity-modulated light source, the macroscopic wave of the density of light energy, called 'photon density wave', forms in the highly scattering medium. The properties of PDW depend on the type of

the source modulation and on the local optical properties of the medium, which are the scattering coefficient μ_s [cm^{-1}] and the absorption coefficient μ_a [cm^{-1}].

Because of the complexity and incoherence of the macroscopic electromagnetic field in highly scattering media, i.e. media with $\mu_a \ll \mu_s$, the fundamental Maxwell equations of electrodynamics do not provide a convenient approach to the solution of the problem of light propagation in such media at distances much larger than l . Therefore, statistical approaches have been developed, such as the photon transport model and its diffusion approximation. In the photon transport model the light is characterized by the radiance $L(\mathbf{r}, \hat{\Omega}, t)$ [$\text{W cm}^{-2} \text{steradian}^{-1}$] (where the steradian is the unit solid angle), which is the power of radiation near the point $\mathbf{r}$ propagating within a small solid angle around the direction $\hat{\Omega}$ at time t . The photon transport model accounts for the possible nonisotropy of the radiation flux. For the given spatio-temporal distribution of the optical properties, μ_a and μ_s , and for the given spatial and angular distribution of light source power $S(\mathbf{r}, \hat{\Omega}, t)$ [$\text{W cm}^{-3} \text{steradian}^{-1}$] the radiance $L(\mathbf{r}, \hat{\Omega}, t)$ can be found from the linear radiation transfer equation, also called the photon transport equation, or simply the transport equation (TE):

$$\frac{1}{v} \frac{\partial L(\mathbf{r}, \hat{\Omega}, t)}{\partial t} + \nabla \cdot L(\mathbf{r}, \hat{\Omega}, t) \hat{\Omega} + (\mu_s + \mu_a) L(\mathbf{r}, \hat{\Omega}, t) = \mu_s \int L(\mathbf{r}, \hat{\Omega}', t) f(\hat{\Omega}, \hat{\Omega}') d\hat{\Omega}' + S(\mathbf{r}, \hat{\Omega}, t) \quad (1)$$

where $f(\hat{\Omega}, \hat{\Omega}')$ is the phase function, which represents the portion of light energy scattered from the direction $\hat{\Omega}$ to the direction $\hat{\Omega}'$ and v is the speed of light in the medium. TE is equivalent to the Boltzmann transport equation describing the transport of particles undergoing scattering.

Eq. (1) is difficult to solve even numerically. Therefore, a hierarchy of approximations to the PTM was developed. This hierarchy, known as the P_N approximation, is based on the expansion of the radiance in a series of spherical harmonics $Y_{nm}(\hat{\Omega})$ truncated at $n=N$. In the P_1 approximation the coefficients of the series are proportional to the radiation fluence

$$\Phi(\mathbf{r}, t) = \int L(\mathbf{r}, \hat{\Omega}, t) d\hat{\Omega} \quad (2)$$

and the flux

$$J(\mathbf{r}, t) = \int L(\mathbf{r}, \hat{\Omega}, t) \hat{\Omega} d\hat{\Omega} \quad (3)$$

both having units of [W cm^{-2}]. By substituting the P_1 series for $L(\mathbf{r}, \hat{\Omega}, t)$ and $S(\mathbf{r}, \hat{\Omega}, t)$ into Eq. (1) and assuming isotropic light sources and sufficiently slow change of source intensity, one can obtain the equation that includes only $\Phi(\mathbf{r}, t)$ as the unknown. Usually, this equation

$$v\mu_a U(\mathbf{r}, t) + \frac{\partial U(\mathbf{r}, t)}{\partial t} - D\Delta U(\mathbf{r}, t) = Q(\mathbf{r}, t) \quad (4)$$

is written in terms of the value $U(\mathbf{r}, t) = \frac{1}{v} \Phi(\mathbf{r}, t)$ [J cm^{-3}], which has units of energy density, and is called the photon density. In Eq. (4) $D = v/(3\mu_a + 3\mu'_s)$ [cm^2/s] is the light diffusion coefficient, and $\mu'_s = \mu_s(1 - g_1)$ [cm^{-1}] is the reduced scattering coefficient; g_1 is the average cosine of the scattering angle. The source term $Q(\mathbf{r}, t)$ [$\text{J cm}^{-3} \text{s}^{-1}$] in the right-hand side of the Eq. (4) describes the spatial distribution of light sources (in the isotropic approximation, i.e., neglecting the dipole and higher momenta of $S(\mathbf{r}, \hat{\Omega}, t)$) and the temporal modulation of source intensity.

Eq. (4) is mathematically equivalent to the equation describing the density of the medium consisting of the particles undergoing linear diffusion. Therefore, it is called the diffusion equation (DE), and the P_1 approximation is also known as the diffusion approximation. The diffusion approximation is valid under the following three conditions: (a) the light sources are isotropic or the distance between the source and the detector is much larger than l ; (b) characteristic source modulation frequencies ν are low enough that $v\mu'_s/(2\pi\nu) \gg 1$; and (c) $\mu_a \ll \mu'_s$. In the biomedical applications of PDWI the condition (a) is fulfilled when the source-detector distance is larger than 1 cm. The condition (b) is valid when the characteristic modulation frequencies of the light source are less than 1 GHz. The condition (c) is fulfilled in most biological tissues, for which the scattering is highly isotropic, i.e. $g_1 \ll 1$. Thus, the forward problem of PDWI, i.e., the modeling of light propagation, can be solved using the diffusion approximation in a large variety of situations.

PDWs described by Eq. (4) are the scalar damped traveling waves, characterized by the coherent changes of light energy (photon density) in different locations on time intervals from microseconds to nanoseconds. Usually pulsed or harmonically modulated light sources are used to generate PDWs. The properties of the PDWs from a harmonic source are fundamental, because the PDW from the source of any type of modulation can be considered as a superposition of harmonic waves from sources having different frequencies using the Fourier transform.

In order to get an idea of the basic properties of PDW, one can consider the analytical solution of (4) for the case of a harmonically modulated point-like source placed in an infinite homogeneous scattering medium. This solution is

$$U(r, t) = U_{dc}(r) + U_{ac}(r) \exp[-i\omega t + i\phi(r)] \quad (5)$$

where U_{ac} , U_{dc} , and ϕ are the ac, dc and phase, respectively, of the wave measured at the distance r from the source, and $\omega = 2\pi\nu$. U_{ac} , U_{dc} , and ϕ depend on the medium optical properties, source intensity Q_0 , modulation amplitude A_0 , and initial phase ψ_0 as

$$U_{ac}(r) = \frac{Q_0 A_0}{4\pi D} \frac{\exp\left[-r\left(\frac{v\mu_a}{2D}\right)^{1/2} \left((1+x^2)^{1/2} + 1\right)^{1/2}\right]}{r} \quad (6a)$$

Fig. 1 Equiphasic surfaces of the PDW induced by a point source in a semi-infinite homogeneous medium (solid lines) and in a medium including heterogeneity (dashed lines).

$$U_{dc}(r) = \frac{Q_0}{4\pi D} \frac{\exp\left[-r\left(\frac{\nu\mu_a}{D}\right)^{1/2}\right]}{r} \quad (6b)$$

$$\phi(r) = r\left(\frac{\nu\mu_a}{2D}\right)^{1/2} \sqrt{(1+x^2)^{1/2} - 1} \quad (6c)$$

where $x = \omega/(\nu\mu_a)$. Eqs. (5)–(6) describe a spherical wave whose wavelength at $\mu_a = 0.1 \text{ cm}^{-1}$ and $\mu'_s = 8 \text{ cm}^{-1}$ (typical for biological tissues) and at modulation frequency $\nu = 100 \text{ MHz}$, is close to 35 cm, so that the phase of the wave changes approximately by 10° per cm. In the same time, the wave decays exponentially at a distance of about 3 cm, so that PDWs are strongly damped. A similar analytical solution in the form of a spherical wave can be obtained for the case of a semi-infinite homogeneous medium and point source placed on the surface of the medium (see Fig. 1). These analytical solutions are employed to measure μ_a and μ'_s of the homogeneous medium. The method is based on fitting measured ac, dc, and phase of the PDW as functions of source–detector distance by the analytical solution.

Inhomogeneities in the optical properties of a turbid medium cause distortion of the PDW from sphericity (see Fig. 1). PDWs in homogeneous media of limited size or with strong surface curvature also usually have complex structure. For a limited number of configurations one can obtain solutions to the DE using analytical methods of mathematical physics, such as the method of Green's functions. However, in practice the complexity of the inhomogeneities and surfaces usually requires numerical solution of the DE. This can be achieved using numerical methods for the solution of partial differential equations, such as the finite element method and the finite difference method. The finite difference method can also be used to solve the TE. This may be necessary in situations when the DE is not valid, for example to accurately account for the influence of the cerebrospinal fluid (which has relatively low scattering) on light transport in the human skull. However, the solution of the TE requires formidable computational resources, which increase proportionally to the volume of the medium. Therefore, hybrid DE-TE methods were developed, in which DE is used to describe light propagation in most of the medium except small low-scattering areas described by the TE.

One should note that although the term 'photon' suggests quantum properties of light, no consistent application of quantum theory to problems related to PDWI has been developed so far. Also, it should be noted that the notion of a photon as a particle of light having certain energy, momentum, and localization at the same time is not completely consistent with quantum electrodynamics. However, since the theoretical models of light transport in a scattering medium (such as TE and DE) are mathematically equivalent to the models describing systems of randomly moving particles, the notion of a photon as a 'particle of light' may be accepted as adequate and is widely used in the limits of PDWI.

Inverse Problem and Imaging Algorithm

Mathematically the forward problem can be expressed in the form of a general nonlinear operator F :

$$G = F[\{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\}] \quad (7)$$

where G is the set of measured values (ac, dc, and phase), $\mathbf{r}$ is the coordinate vector of a medium element (voxel), and $\{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\}$ denotes the set of tissue optical properties corresponding to whole collection of voxels. The problem of finding the spatial distribution of medium optical properties can be formalized as

$$\{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\} = F^{-1}[G] \quad (8)$$

Neither the transport model nor the diffusion model allow inversion in a closed analytical form for a general boundary configuration and spatial distribution of optical properties. The basic reason for the complexity of the inverse problem is in the complexity of the light paths in the highly scattering medium. This situation is opposite to that in CT, where the x-ray radiation propagates through the medium along straight lines almost without scattering, which significantly simplifies the forward problem and allows its analytical inversion. From the mathematical point of view, the complexity of the inverse problem of PDWI is due to its nonlinearity and ill-posedness. Only approximate methods of inversion have been developed so far.

The simplest method is called backprojection by analogy with the method of the same name used in CT. The method attempts to reconstruct the actual spatial distribution of the optical properties μ_a and/or μ'_s from the 'measured' bulk values μ_a^m and μ'_s^m obtained at a variety of locations assuming homogeneity of the medium. The measured values are considered as a result of the volumetric 'projection'

$$\{\mu_a^m(\mathbf{r}), \mu'_s^m(\mathbf{r})\} = \int \{\mu_a(\mathbf{r}'), \mu'_s(\mathbf{r}')\} h(\mathbf{r} - \mathbf{r}') d^3\mathbf{r}' \quad (9)$$

of the actual distribution, where $\mathbf{r}$ and $\mathbf{r}'$ are the locations of the measurement and reconstruction, respectively. A weight function $h(\mathbf{r})$ accounts for the contribution of the particular region to a measured value and should be derived from the forward model. Different versions of the backprojection method use different weight functions $h(\mathbf{r})$. In the backprojection method the values of μ_a and/or μ'_s are obtained by inverting the convolution (9). In practice the convolution integral is usually estimated by a sum over a limited number of voxels for a limited number of measurements. Therefore, the inversion of the convolution reduces to the solution of the set of algebraic equations corresponding to (9). The advantage of the method is high speed, which allows real-time imaging of the dynamic processes, for example, functional hemodynamic changes in the brain. However, the backprojection method provides a phenomenological rather than a self-consistent inversion of the forward problem, and its quantitative accuracy is low.

A more consistent method is based on the perturbation approach to the solution of the inverse problem (8). If we have an estimate $\{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\}_e$ that is close to the ideal solution, then $G_e = F[\{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\}_e]$ (see Eq. (7)) is close to S . Then the difference $G - G_e$ can be written as a Taylor series:

$$G - G_e = J[\{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\}_e] \{\Delta\mu_a(\mathbf{r}), \Delta\mu'_s(\mathbf{r})\} + \dots \quad (10)$$

where $J[\dots]$ is the Jacobian, and $\{\Delta\mu_a(\mathbf{r}), \Delta\mu'_s(\mathbf{r})\} = \{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\} - \{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\}_e$. Neglecting terms after the first one in (10), the problem of finding the correction $\{\Delta\mu_a(\mathbf{r}), \Delta\mu'_s(\mathbf{r})\}$ to the estimate $\{\mu_a(\mathbf{r}), \mu'_s(\mathbf{r})\}_e$ reduces to the calculation of the Jacobian and to the solution of a linear algebraic equation.

This approach provides a basis for the PDWI algorithm, which is the following. First one makes an initial guess at the optical properties of the medium. Then one calculates the ac, dc, and phase of the PDW using a model of light propagation through the tissue and the geometry of the source–detector configuration. The calculated values are compared with the measured ones. If the error is above a set tolerance level, one calculates corrections to the current values of μ_a and μ'_s by solving Eq. (10). The algorithm is completed when the required error level is achieved. Thus, the PDWI algorithm iteratively applies both the forward and inverse problems. Since at each of many iterations one should solve the forward problem, which in the simplest case is a partial differential equation, the algorithm typically requires considerable computational resources.

One should note that the success of the method is largely dependent on the closeness of the initial guess to the actual values of the optical properties. In many studies the 'first guess' of the tissue optical properties was obtained by measuring the bulk absorption and reduced scattering coefficients. However, because of the ill-posedness of the inverse problem, homogeneous initial conditions did not always lead to the correct reconstruction. A more productive approach to the problem of the initial conditions is to assign approximate initial values of the optical properties known for example from *in vitro* measurements to different structures revealed by nonoptical imaging techniques, such as magnetic resonance imaging (MRI) or CT.

Applications

PDWI was proposed and developed as a noninvasive biomedical imaging technique. Although the spatial resolution of PDWI cannot compete with that of CT or MRI, PDWI has the advantages of low cost, high temporal resolution, and high biochemical specificity. The latter is based on the optical spectroscopic approach. Biological tissues are relatively transparent to light in the near-infrared band between 700 and 1000 nm (a near-infrared window). The major biological chromophores in this window are oxy- and deoxyhemoglobin, and water. One can separate contributions of these chromophores into light absorption by employing light sources at different wavelengths. Multi-wavelength PDWI can also be used to measure the redox state of the cytochrome oxidase, which is the terminal electron acceptor of the mitochondrial electron transport chain and responsible for 90% of cellular oxygen consumption.

One of the hot topics in cognitive neuroscience is the hemodynamic mechanism of the oxygen supply to neurons and removal of products of cerebral metabolism. High temporal resolution and biochemical specificity make PDWI a unique noninvasive tool for studies of functional cerebral hemodynamics, although light can penetrate no deeper than the very surface of the adult brain. Fig. 2 displays a typical arrangement of light sources and detectors used in PDWI of functional cerebral hemodynamics, and the images of the activated area in the brain.

Because of its low cost, noninvasiveness, and compact size of the optical sensors, PDWI is also considered to be a promising tool for mammography and structural imaging of anomalies in the brain. PDWI is an especially promising tool for neonatology, because the infant tissues have low absorption.

PDWI instruments employ lasers, light-emitting diodes and gas-discharge tubes as sources of light. Among the detectors there are photomultiplier tubes, avalanche photodiodes, and CCD cameras. Both sources and detectors can be coupled with the tissue by means of optical fibers. A number of commercially produced near-infrared instruments for PDWI are available on the market.

Fig. 2 (a) Geometrical arrangement of the 16 sources and two detectors on the head of a human subject. Each one of the eight small red circles (numbered 1–8) represents one pair of source fibers at 758 and 830 nm. Two larger green circles represent detector fiber bundles. The rectangle inside the head outline is the $4 \times 9 \text{ cm}^2$ imaged area. (b) Maps of oxyhemoglobin ($[\text{HbO}_2]$, left panels) and deoxyhemoglobin ($[\text{Hb}]$, right panels) concentration changes at rest (top) and at the time of maximum response during the third tapping period (bottom). The measurement protocol involved hand-tapping with the right hand (contralateral to the imaged brain area). Adapted with permission from Franceschini MA, Toronov V, Filiaci M, Gratton E, Fantini S (2000) On-line optical imaging of the human brain with 160-ms temporal resolution. *Optics Express* 6(3), 49–57 (Figs. 1 and 4).

According to the type of source modulation, there are three groups of instruments: frequency domain (harmonically modulated sources), time domain (pulsed sources), and steady state. Steady-state instruments are simpler and cheaper than frequency-domain and time-domain ones, but their capabilities are much lower. Time-domain instruments can theoretically provide a maximum of information about the tissue structure, but technically it is difficult to build a time-domain instrument with high temporal resolution and high signal-to-noise ratio. Frequency-domain instruments provide temporal resolution up to several milliseconds and have high quantitative accuracy in the determination of optical properties.

Three-Dimensional Field Transformations

R Piestun, University of Colorado, Boulder, CO, USA

Introduction

Conventional optical imaging is understood as an isomorphic mapping from an object space onto an image space. The object space is composed of scattering or emitting objects. The scattering objects can be opaque, transparent, or partially absorbing, while emitting objects can be as diverse as stars in astronomical imaging or fluorescent molecules in microscopic imaging. The image space is an optical field representation of the object.

In most classical applications of optical imaging the goal is to optimize the mapping between one plane in the object space and one plane in the image space. Modern optical systems, though, are aimed at acquiring three-dimensional information regarding the object. The image is thus a three-dimensional field representation of the object.

While many imaging systems are aimed at obtaining visually appealing images, many modern imaging systems register the field information in some type of sensitive device such as film or CCD cameras for later processing. This processing is typically performed electronically by a computer and the final image is ultimately a mathematical digital representation of the object. This type of imaging is called computational imaging. An example of computational imaging is optical tomography, which involves the registration of a set of images that do not necessarily resemble the object, and off-line digital processing to obtain a three-dimensional representation of the object.

In this article we will focus on imaging in the conventional sense but will also focus on the three-dimensional aspects of the image.

Geometrical Optics Transformations

In many optical problems it is appropriate to consider the wavelength of the electromagnetic wave as infinitely small. This approximation is the origin of the field of geometrical optics in which the propagation of light is formulated in terms of geometrical laws. Accordingly, the energy is transported along light rays and their trajectories are determined by certain differential or integral equations that can be directly derived from Maxwell's equations. One of these formulations uses Fermat's principle that states the principle of the shortest optical path. The optical path between two points P_1 and P_2 is defined as:

$$OP = \int_{P_1}^{P_2} n(P) ds \quad (1)$$

where n is the refractive index of the medium. Fermat's principle states that the optical path of a real ray is always a local minimum.

In ideal optical imaging systems, every point P_o of the so-called object space will generate a sharp image point P_i , that is a point where infinite rays emerging from P_o pass through P_i . Perfect imaging occurs when every curve defined by object points is geometrically similar to its image. Perfect imaging can occur between three-dimensional spaces or between surfaces.

An interesting result of geometrical optics is Maxwell's theorem. This theorem states that if an optical instrument produces a sharp image of a three-dimensional domain, the optical length of any curve in the object is equal to the optical length of its image. More explicitly, if the object space has index n_o and the image space index n_i , the theorem states that:

$$\int_{C_o} n_o ds_o = \int_{C_i} n_i ds_i \quad (2)$$

where C_i is the image of the object curve C_o .

An important consequence of Maxwell's theorem is a theorem by Carathéodory which states that any imaging transformation has to be a projective transformation, an inversion, or a combination of them. Another consequence of this theorem is that if the two media are homogeneous, perfect imaging can only occur if the magnification is equal to the ratio of the refractive indices in the object and image space. If the media have the same index, the imaging is trivial with unit magnification. The simplest example of a perfect imaging instrument is a planar mirror. Therefore, if we want to achieve nontrivial imaging between homogeneous spaces with equal index, we must give up either the perfect imaging (similarity) or the sharpness of the image.

The geometrical optics approximation is very useful in the design of optical imaging systems. However, it fails to provide a complete description of wave optical effects, notably diffraction. Therefore, the following sections provide a description of field transformations based on wave optics.

Systems Approach to 3D Imaging

In this article we deal with linear imaging systems. Hence the relation between three-dimensional (3D) input (object) signals and 3D output (image) signals can be completely specified by the 3D impulse response or point spread function (PSF) of the system $h(x, y, z; x', y', z')$. This function specifies the response of the system at image space coordinates (x, y, z) to a δ -function input (point source) at object coordinates (x', y', z') . The optical system object and image signals are related by the superposition integral:

$$i(x, y, z) = \int \int \int_{\Omega} o(x', y', z') h(x, y, z; x', y', z') dx' dy' dz' \quad (3)$$

where Ω is the object domain. It is clear that for a generic linear imaging system the image signal is completely specified by the response to input impulses located at all possible points of the image domain.

If the system is shift invariant, the PSF due to a point source located anywhere in the object domain will be a linearly shifted version of the response due to a reference point source. This approximation is in general not valid and the system's PSF is a function of the position of the point source in the object domain. Shift invariance is traditionally divided into radial and axial shift invariance. Radial shift variance is the change in the image of a point source as a function of its radial distance from the optical axis. Radial shift variance is caused by lens aberrations. Axial shift variance is the change in the image of a point source as a function of its axial position, z' , in the object space. Axial shift variance is inherent to any rotationally symmetric lens system because they can only have one pair of conjugate surfaces, i.e., object-image corresponding surfaces.

In most practical cases the image is detected at a single plane, $z = z_1$ transverse to the optical axis Oz . In those situations, we need to specify the impulse response on this plane:

$$h(x, y, z_1; x', y', z') = h_z(x, y; x', y') \quad (4)$$

The condition for lateral shift invariance is then expressed as $h_z(x, y; x', y') = \tilde{h}_z(x - x', y - y')$. In this case, the superposition integral is a two-dimensional (2D) convolution and it is possible to define the transfer function of the system that is the 2D Fourier transform of the impulse response $\tilde{h}_z(x - x', y - y')$.

Point Spread Function for Coherent, Incoherent, and Partially Coherent Illumination

The input-output relations of an optical imaging system relate different magnitudes according to the type of illumination. If the illumination is coherent, the system is linear in the complex amplitude, while if the illumination is fully incoherent the system is linear in intensity. The 3D impulse response of the incoherent (h_{Inc}) and coherent (h_{Coh}) systems are related as follows:

$$h_{\text{Inc}}(x, y, z; x', y', z') = |h_{\text{Coh}}(x, y, z; x', y', z')|^2 \quad (5)$$

Notwithstanding, many optical systems cannot be considered fully coherent or fully incoherent. In these situations the system is said partially coherent. If the optical path differences within the optical system are much shorter than the coherence length of the illumination, the light effectively has complete temporal coherence and the magnitude of interest is the mutual intensity. The mutual intensity is defined as the statistical correlation of the complex wavefunction $U(\mathbf{r}, t)$ between different points in space:

$$J(\mathbf{r}_1, \mathbf{r}_2) = \langle U^*(\mathbf{r}_1, t) U(\mathbf{r}_2, t) \rangle \quad (6)$$

where $\mathbf{r}_i = (x_i, y_i, z_i)$, $i = 1, 2$. The illumination is then called quasi-monochromatic. For the case of partially coherent quasi-monochromatic illumination, the system is linear in the mutual intensity. The partially coherent impulse response (h_{PC}) is also related to the coherent impulse response as follows:

$$h_{\text{PC}}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}'_1, \mathbf{r}'_2) = h_{\text{Coh}}^*(\mathbf{r}_1; \mathbf{r}'_1) h_{\text{Coh}}(\mathbf{r}_2; \mathbf{r}'_2) \quad (7)$$

The 3D superposition integral that relate object and image mutual intensities is now:

$$J_{\text{image}}(\mathbf{r}_1, \mathbf{r}_2) = \int \int \int_{\Omega} h_{\text{PC}}(\mathbf{r}_1, \mathbf{r}_2; \mathbf{r}'_1, \mathbf{r}'_2) \times J_{\text{object}}(\mathbf{r}'_1, \mathbf{r}'_2) d\mathbf{r}'_1 d\mathbf{r}'_2 \quad (8)$$

Therefore, we conclude that knowledge of the coherent PSF is enough to characterize the optical system for illumination of various degrees of coherence.

Spatial Frequency Content of the 3D Point Spread Function

As previously stated, the coherent impulse response of the optical system completely defines its imaging characteristics. Therefore, it is justified to wonder what the limitations are in the specification of this response. In this section we analyze the frequency domain of coherent and incoherent impulse responses.

The impulse response of the optical system will satisfy the corresponding wave equations regardless of the particulars of the optical system. In particular, assuming a homogeneous isotropic medium in the imaging domain, the coherent response $h(\mathbf{r})$ to an

Fig. 1 Three-dimensional spatial-frequency domain of the coherent point spread function.

impulse at $\mathbf{r}'$ will satisfy the homogeneous Helmholtz equation in the image domain:

$$\nabla^2 h(\mathbf{r}) + k^2 h(\mathbf{r}) = 0 \quad (9)$$

where $h(\mathbf{r})$ is the complex amplitude and $k = 2\pi/\lambda$, with λ the wavelength in the medium. If the field at a given origin of coordinates $z = 0, f(x, y)$, is known, $h(\mathbf{r})$ can be calculated using the angular spectrum representation as follows:

$$h(x, y, z) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} F(f_x, f_y) \exp[i2\pi(f_x x + f_y y + f_z z)] df_x df_y \quad (10)$$

where $f_z = \sqrt{\lambda^{-2} - (f_x^2 + f_y^2)}$ and $F(f_x, f_y) = \text{FT}\{f(x, y)\}$; FT represents a 2D Fourier transformation and f_x, f_y are the spatial frequencies along the x and y axes respectively.

Eq. (10) can be written as a 3D integral as follows:

$$h(x, y, z) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} F(f_x, f_y) \cdot \delta\left[f_z - \sqrt{\lambda^{-2} - f_x^2 - f_y^2}\right] \exp[i2\pi(f_x x + f_y y + f_z z)] df_x df_y df_z \quad (11)$$

where δ represents the dirac impulse. Next we represent the 3D impulse response $h(x, y, z)$ as a 3D Fourier decomposition:

$$h(x, y, z) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} H(f_x, f_y, f_z) \exp[i2\pi(f_x x + f_y y + f_z z)] df_x df_y df_z \quad (12)$$

where $H(f_x, f_y, f_z) = \text{FT}^{3D}\{h(x, y, z)\}$. Comparing Eqs. (11) and (12) we can infer that:

$$H(f_x, f_y, f_z) = F(f_x, f_y) \cdot \delta\left[f_z - \sqrt{\lambda^{-2} - f_x^2 - f_y^2}\right] \quad (13)$$

This relation implies that the domain of the Fourier transform of the impulse response is confined to a spherical shell of radius $1/\lambda$. Alternatively, $H(f_x, f_y, f_z)$ is zero everywhere, except from the surface of the sphere.

The previous derivation did not consider any limitation in the range of spatial frequencies allowed through the system. We now assume a finite aperture that will introduce an effective radial cutoff frequency $f_c < 1/\lambda$ and will further limit the spatial spectral domain of $h(x, y, z)$. This is depicted in Fig. 1. Note that the transverse and longitudinal spatial frequencies are related, hence the longitudinal spatial frequencies are located within a bandpass of width $\Delta f_z = 1 - \sqrt{\lambda^{-2} - f_c^2}$.

Let us now consider the frequency content of possible incoherent PSFs. From Eq. (5) we derive the 3D Fourier transform of the incoherent impulse response:

$$\begin{aligned} H_{\text{Inc}}(f_x, f_y, f_z) &= \text{FT}\{h_{\text{Inc}}(x, y, z; x' y', z')\} \\ &= \text{FT}\{|h_{\text{Coh}}(x, y, z; x' y', z')|^2\} \\ &= H \otimes H(f_x, f_y, f_z) \end{aligned} \quad (14)$$

where $\otimes$ represents a 3D correlation. The domain of H_{Inc} now becomes a volume of revolution as shown in Fig. 2. Moreover, because h_{Inc} is real, H_{Inc} is conjugate symmetric, i.e., $H_{\text{Inc}} = H_{\text{Inc}}^*$. Now, the transverse cutoff frequency is $f_c^{\text{Inc}} = 2f_c$ while the longitudinal cutoff frequency is $f_{\text{cl}}^{\text{Inc}} = 2\Delta f_z$.

Diffraction Calculation of the 3D Point Spread Function

The 3D-image field created by a point source in the object space can be predicted by proper modeling of the optical system. In the absence of aberrations, the distortion of the PSF is originated in the diffraction created by the limiting aperture of the optical system. Diffraction is thus the ultimate limitation to the resolution of the optical system. Under the design conditions of the

Fig. 2 Three-dimensional spatial-frequency domain of the incoherent point spread function.

Fig. 3 Diffraction of a spherical wave by a planar aperture.

system, i.e., assuming all aberrations are corrected, the image of a point source is the diffraction pattern produced when a spherical wave converging to the (geometrical) image point is diffracted by the limiting aperture of the system. This is called a diffraction limited image.

There are many formulations to describe the 3D diffraction pattern obtained with a converging wave through an aperture. Here we review the Kirchhoff formulation. Let us consider the aperture A and the field at a point P_d originated from a converging spherical wave focused at point P_F (see **Fig. 3**). We define the vectors $\mathbf{r}$ joining a generic point on the aperture P_0 and P_F , and $\mathbf{s}$ joining P_0 and P_d . The Kirchhoff formulation states that the complex amplitude $U(P_d/P_F)$ is the integral over the aperture of the complex amplitude at each point propagated to P_d by a spherical wave $\exp(iks/s)$ modified by the directional factor $\cos(\hat{\mathbf{n}}, \mathbf{s}) - \cos(\hat{\mathbf{n}}, \mathbf{r})$. $\hat{\mathbf{n}}$ is the unit vector normal to the aperture:

$$U(P_d/P_F) = \frac{-iC}{2\lambda} \int_A \frac{\exp[-ik(r-s)]}{rs} [\cos(\hat{\mathbf{n}}, \mathbf{r}) - \cos(\hat{\mathbf{n}}, \mathbf{s})] dS \quad (15)$$

where $r = \|\mathbf{r}\|$, $s = \|\mathbf{s}\|$, and C is the amplitude of the spherical wave.

The directional factor varies slowly and in many situations can be approximated by a constant equal to 2 for small image-field angles. The amplitude over the aperture is also slowly varying and can be approximated by a constant, i.e., $C/r \approx C_0$. Different formulations of the Kirchhoff integral differ in the estimates of the factor $1/s$ and the phase $k(r-s)$. For example, one such formulation leads to the following expression for the 3D diffraction pattern for a focal point on the axis of an optical system with circular aperture:

$$U(P_d/P_F) = \frac{-ika^2 C_0}{z_d} \exp\left[ik\left(z_d - z_F + \frac{r_d^2}{2z_d}\right)\right] \times \int_0^1 J_0\left(\frac{k\rho r_d}{z_d}\right) \exp\left[\frac{-ika^2 \rho^2 (z_d - z_F)}{2z_d z_F}\right] \rho d\rho \quad (16)$$

where a is the radius of the aperture, r_d is the radial coordinate of P_d , and ρ is the radial coordinate of P_0 .

To illustrate the use of **Eq. (16)**, we calculated the intensity around the focus of a spherical wave diffracted through a circular aperture of radius $a=0.5$ cm, focusing at distance $z_F=4$ cm from the screen. We assumed the wavelength to be $\lambda=0.5$ μ . **Fig. 4** depicts the magnitude of the complex amplitude in a meridional plane near the focus of the converging spherical wave.

Models that take into account off-axis focal points have also been developed. For the most accurate calculations, it is necessary to consider the full electromagnetic nature of the optical field.

Fig. 4 Lines of equal intensity in a meridional plane near the focus of a converging spherical wave diffracted at a circular aperture ($\lambda = 0.5 \mu$, $a = 0.5$ cm, $z_F = 4$ cm).

Conclusions

Classical imaging theory can be applied to the 3D imaging transformation from object to image. The systems approach to the imaging problem implies that knowledge of the 3D coherent PSF suffices to predict the 3D response of the system under illumination of varying degrees of coherence. The PSF response can be predicted using well-known formulations of diffraction.

Volume Holographic Imaging

G Barbastathis, Massachusetts Institute of Technology, Cambridge, MA, USA

© 2005 Published by Elsevier Ltd.

Volume holographic imaging (VHI) refers to a class of imaging techniques which use a volume hologram in at least one location within the optical path. The volume hologram acts as a 'smart lens,' which processes the optical field to extract spatial information in three dimensions (lateral as well as longitudinal) and spectral information.

Fig. 1 is a generic VHI system. The object is either illuminated by a light source (e.g., sunlight or a pump laser) as shown in the figure, or it may be self-luminous. Light scattered or emitted by the object is first transformed by an objective lens and then illuminates the volume hologram. The role of the objective is to form an intermediate image which serves as input to the volume hologram. The volume hologram itself is modeled as a three-dimensional (3D) modulation $\Delta\epsilon(\mathbf{r})$ of the dielectric index within a finite region of space. The light entering the hologram is diffracted by $\Delta\epsilon(\mathbf{r})$ with efficiency η , defined as

$$\eta = \frac{\text{Power diffracted by the volume hologram}}{\text{Power incident to the volume hologram}} \quad (1)$$

We assume that diffraction occurs in the Bragg regime. The diffracted field is Fourier-transformed by the collector lens, and the result is sampled and measured by an intensity detector array (such as a CCD or CMOS camera).

Intuitively, we expect that a fraction of the illumination incident upon the volume hologram is Bragg-matched and is diffracted towards the Fourier-transforming lens. The remainder of the incident illumination is Bragg-mismatched, and as result is transmitted through the volume hologram un-diffracted. Therefore, the volume hologram acts as a filter which admits the Bragg-matched portion of the object and rejects the rest. When appropriately designed, this 'Bragg imaging filter' can exhibit very rich behavior, spanning the three spatial dimensions and the spectral dimension of the object.

To keep the discussion simple, we consider the specific case of a transmission geometry volume hologram, described in **Fig. 2**. The volume hologram is created by interfering a spherical wave and a planewave, as shown in **Fig. 2(a)**. The spherical wave originates at the coordinate origin. The planewave is off-axis and its wavevector lies on the xz plane. As in most common holographic systems, the two beams are assumed to be at the same wavelength λ , and mutually coherent. The volume hologram results from exposure of a photosensitive material to the interference of these two beams.

First, assume that the object is a simple point source. The intermediate image is also approximately a point source, that we refer to as 'probe,' located somewhere in the vicinity of the reference point source. Assuming the wavelength of the probe source is the same as that of the reference and signal beams, volume diffraction theory shows that:

- (i) If the probe point source is displaced in the y direction relative to the reference point source, the image formed by the volume hologram is also displaced by a proportional amount. Most common imaging systems would be expected to operate this way.
- (ii) If the probe point source is displaced in the x direction relative to the reference point source, the image disappears (i.e., the detector plane remains dark).
- (iii) If the probe point source is displaced in the z direction relative to the reference point source, a defocused and faint image is formed on the detector plane. 'Faint' here means that the fraction of energy of the defocused probe transmitted to the detector plane is much smaller than the fraction that would have been transmitted if the probe had been at the origin.

Fig. 1 Volume holographic imaging (VHI) system.

Fig. 2 (a) Recoding of a transmission-geometry volume hologram with a spherical wave and an off-axis plane wave with its wave-vector on the xz plane. (b) Imaging of a probe point source that replicates the location and wavelength of the reference point source using the volume hologram recorded in part (a). (c) Imaging of a probe point source at the same wavelength but displaced in the y direction relative to the reference point source. (d) Imaging of a probe point source at the same wavelength but displaced in the x direction relative to the reference point source. (e) Imaging of a probe point source at the same wavelength but displaced in the z direction relative to the reference point source. (f) 'Bragg slitting:' Imaging of an extended monochromatic, spatially incoherent object using a volume hologram recorded as in (a). (h) Multiplex imaging of several slices using a volume hologram formed by multiple exposures.

Fig. 2 (Continued).

Fig. 2 (Continued).

Now consider an extended, monochromatic, spatially incoherent object and intermediate image, as in Fig. 2(f). According to the above description, the volume hologram acts as a 'Bragg slit' in this case: because of Bragg selectivity, the volume hologram transmits light originating from the vicinity of the y axis, and rejects light originating anywhere else. For the same reason, the volume hologram affords depth selectivity (like the pinhole of a confocal microscope). The width of the slit is determined by the recording geometry, and the thickness of the volume hologram. For example, in the transmission recording geometry of Fig. 2(a), where the reference beam originates a distance z_0 away from the hologram, the planewave propagates at angle θ with respect to the optical axis z (assuming $\theta \ll 1$ radian), and the hologram thickness is L (assuming $L \ll z_0$), the width of the slit is found to be

$$\Delta x \approx \frac{\lambda z_0}{L\theta} \quad (2)$$

The imaging function becomes richer if the object is polychromatic. In addition to its Bragg slit function, the volume hologram exhibits then dispersive behavior, like all diffractive elements. In this particular case, dispersion causes the hologram to image simultaneously multiple Bragg slits, each at a different color and parallel to the original slit at wavelength λ , but displaced along the z axis. Light from all these slits finds itself in focus at the detector plane, thus forming a 'rainbow image' of an entire slice through the object, as shown in Fig. 2(g).

To further exploit the capabilities of volume holograms, we recall that in general it is possible to 'multiplex' (superimpose) several volume gratings within the same volume by successive exposures. In the imaging context, suppose that we multiplex several gratings similar to the grating described in Fig. 2(a) but with spherical reference waves originating at different locations and plane signal waves at different orientations. When the multiplexed volume hologram is illuminated by an extended polychromatic source, each grating forms a separate image of a rainbow slice, as described earlier. By spacing appropriately the angles of propagation of the plane signal waves, we can ensure that the rainbow images are formed on nonoverlapping areas on the detector plane, as shown in Fig. 2(h). This device is now performing true four-dimensional (4D) imaging: it is separating the spatial and spectral components of the object illumination so that they can be measured independently by the detector array. Assuming the photon count is sufficiently high and the number of detector pixels is sufficient, this 'spatio-spectral slicing' operation can be performed in real time, without need for mechanical scanning.

The complete theory of VHI in the spectral and spatial domains is given in the Further Reading section below. Experimental demonstrations of VHI have been performed in the context of a confocal microscope where the volume hologram performs the function of a 'Bragg pinhole' as well as a real-time 4D imager. The limited diffraction efficiency η of volume holograms poses a major concern for VHI systems. Holograms, however, are known to act as matched filters. It has been shown that the matched filtering nature of volume holograms as imaging elements is superior to other filtering elements (e.g., pinholes or slits) in an information-theoretic sense. Efforts are currently underway to strengthen this property by design of volume holographic imaging elements which are more elaborate than described here.

Wavefront Sensors and Control (Imaging Through Turbulence)

CL Matson, Air Force Research Laboratory, Kirtland, NM, USA

© 2005 Elsevier Ltd. All rights reserved.

Introduction

In many situations, distant objects are imaged using optical or near-infrared imaging systems. Examples include terrestrial surveillance from space, tactical surveillance from airborne imaging systems, and ground-based astronomical imaging. Ideally, the resolution in these images is limited only by the wavelength of light λ used to create the images divided by the imaging system's effective diameter D . The ratio λ/D is called the diffraction limit of the imaging system. Unfortunately, when the imaging system is located in the Earth's atmosphere, it is often atmospheric turbulence fluctuations that limit the level of detail in the long-exposure images, not the diffraction limit of the telescope. For example, the Keck telescopes, located on top of Mauna Kea in Hawaii, are 10 m diameter telescopes that have a diffraction-limited angular resolution of $0.2 \mu\text{rad}$ for an imaging wavelength of $2 \mu\text{m}$. However, atmospheric turbulence limits the achievable resolution in long-exposure images to the order of $1\text{--}5 \mu\text{rad}$ at this wavelength.

The important discovery by Anton Labeyrie in 1970 that short-exposure images of objects retain meaningful diffraction-limited information about the object, where 'short' means that the exposure time is less than the atmospheric turbulence coherence time, has revolutionized imaging through turbulence. Atmospheric coherence times depend upon a number of factors, including wind speeds, wind altitudes, and observation wavelength. At astronomical observatories for visible observation wavelengths, a rule of thumb is that atmospheric turbulence stays essentially constant for exposure times of one to ten milliseconds under average clear-sky weather conditions. A variety of techniques that exploit this discovery have been developed. These techniques can be grouped into three different categories: techniques that remove blurring from the detected intensity images (post-detection compensation), techniques that modify the optical field prior to detecting the light (pre-detection compensation), and hybrid techniques that use both post-detection and pre-detection compensation. In this article, a variety of these techniques are presented that are representative of the myriad of methods that have been developed during the past decades. To simplify the discussion, it is assumed that the blurring due to atmospheric turbulence is the same at every point in the image (isoplanaticity), that the images are formed using incoherent light as emitted by the sun and stars, and that a single filled aperture is used to create the images. Interferometric techniques that use multiple apertures to estimate the mutual coherence function of the optical field and calculate an image from it.

The emphasis in this article is on identifying and removing atmospheric blurring in images. As part of this process, regularization techniques must be included in the image reconstruction algorithms in order to obtain the best possible resolution for an acceptable level of noise. Although regularization techniques are not discussed in this article, information can be found in the Further Reading section at the end of this article.

Imaging and Atmospheric Turbulence

In Fig. 1, a conceptual diagram illustrates the impact that atmospheric turbulence has upon resolution in classical imaging systems. A distant star is being imaged by a telescope/detector system. In the absence of atmospheric turbulence, the field emitted by the star has a planar wavefront over the extent of the lens since the star is a long distance from the imaging system and thus unresolved by the telescope. When imaged by the telescope, the diffraction pattern of the telescope is obtained, resulting in a diffraction-limited image (Fig. 2). However, in the presence of atmospheric turbulence near the telescope, the planar wavefront is randomly distorted by the turbulence, resulting in a corrugated wavefront with a spatial correlation scale given by the Fried parameter r_o . For visible wavelengths, at good astronomical observing sites, r_o ranges from 5 cm to 20 cm. When this corrugated wavefront is converted to an image by the telescope, a distorted image is obtained (Fig. 3). Because atmospheric turbulence is time-varying, the distortions in the image also change over time. If the imaging shutter on the telescope remains open for many occurrences of atmospheric turbulence, the resulting image will be an average of all the individually distorted images, resulting in what is known as the seeing disk (Fig. 4). It is the seeing disk that typically limits spatial resolution in long-exposure images, not the diffraction pattern of the telescope. As a result, the effective spatial resolution in long-exposure images in the presence of atmospheric turbulence is given by λ/r_o , not λ/D .

Atmospheric turbulence distorts a field's wavefront by delaying it in a way that is spatially and temporally random. The origin of these delays is the random variation in the index of refraction of the atmosphere as a result of turbulent air motion brought about by temperature variations. A Fourier optics imaging model is useful in characterizing the effects of atmospheric turbulence on spatial resolution in images. Let $i(\vec{x})$ be an image of an object $o(\vec{x})$ where $\vec{x}$ is a two-dimensional spatial vector, and let $I(\vec{f})$ and $O(\vec{f})$ be their spatial Fourier transforms, where $\vec{f}$ is a two-dimensional spatial frequency vector. In the absence of atmospheric turbulence, the diffraction-limited Fourier transform $I(\vec{f})$ is given by

$$I_d(\vec{f}) = O(\vec{f})H_d(\vec{f}) \quad (1)$$

Fig. 1 Conceptual diagram of imaging through atmospheric turbulence.

Fig. 2 Computer-simulated diffraction-limited image of a point source.

where the subscript 'd' denotes the diffraction-limited case and where $H_d(\vec{f})$ is the diffraction-limited telescope transfer function. In the presence of atmospheric turbulence, the Fourier transform of a long exposure image $i_{le}(\vec{x})$ is given by

$$I_{le}(\vec{f}) = O(\vec{f})H_d(\vec{f})H_{le}(\vec{f}) = I_d(\vec{f})H_{le}(\vec{f}) \quad (2)$$

where the subscript 'le' denotes long exposure. If the turbulence satisfies Kolmogorov statistics, as is typically assumed, then:

$$H_{le}(\vec{f}) = \exp \left[-3.44 \left(\frac{\lambda d |\vec{f}|}{r_o} \right)^{5/3} \right] \quad (3)$$

where d is the distance between the imaging system's exit pupil and detector plane. As can be seen from Eq. (2), the effect of atmospheric turbulence on a long-exposure image is a multiplication of the diffraction-limited image's Fourier transform by a transfer function due to atmospheric turbulence. In Fig. 5, an amplitude plot of a diffraction-limited transfer function is displayed along with an amplitude plot of a long-exposure transfer function for a 2.3 m diameter telescope, an imaging wavelength of

Fig. 3 Computer-simulated short-exposure image of a point source through atmospheric turbulence.

Fig. 4 Computer-simulated long-exposure image of a point source through atmospheric turbulence.

0.5 μm , and an r_0 value of 10 cm. Notice that the long exposure transfer function significantly reduces the amount of high spatial frequency information in an image. Diffraction-limited and long-exposure turbulence-limited images of a binary star are shown in [Figs. 6](#) and [7](#), illustrating the significant loss of spatial resolution brought on by atmospheric turbulence.

Post-Detection Compensation

Speckle Imaging

Labeyrie's 1970 discovery was motivated by his analysis of short-exposure star images. In these images (see [Fig. 3](#)), a number of speckles are present, where the individual speckle sizes are roughly the size of the diffraction-limited spot of the telescope. From this, he realized that high spatial frequency information is retained in short-exposure images, albeit distorted. He then showed that

Fig. 5 Plots of the Fourier amplitudes of the diffraction-limited transfer function (dashed line), Fourier amplitudes of the long-exposure transfer function (dotted line), and the square root of the average short exposure energy spectrum. The spatial frequency axis is normalized to one at the diffraction limit of the telescope.

Fig. 6 Computer-simulated diffraction-limited image of a binary star.

the energy spectra $E_1(\vec{f})$ of the individual short-exposure images can be averaged to obtain an estimate of the average energy spectrum that retains high signal-to-noise ratio (SNR) information at high spatial frequencies. The square root of the average energy spectrum (the amplitude spectrum) of a star, calculated using Labeyrie's method (also known as speckle interferometry), is shown in **Fig. 5**, along with the diffraction-limited and long-exposure amplitude spectra. Notice that meaningful high spatial frequency information is retained in the average amplitude spectrum out to the diffraction limit of the telescope. Because the atmospherically corrupted amplitude spectrum estimate is significantly lower than the diffraction-limited amplitude, a number of short exposure images must be used to build up the SNRs at the higher spatial frequencies.

To reconstruct an image, both the Fourier amplitudes and Fourier phases of the image must be known. In fact, it is well known that the Fourier phase of an image carries most of the information in the image. Because only the Fourier amplitudes are available using Labeyrie's method, other techniques were subsequently developed to calculate the Fourier phase spectrum from a sequence of short-exposure images. Techniques that combine amplitude spectrum estimation using Labeyrie's method along with phase spectrum estimation are called speckle imaging techniques. The two most widely used phase spectrum estimation methods are the Knox-Thompson (or cross spectrum) and bispectrum algorithms. Both of these algorithms calculate Fourier-domain quantities that retain high spatial frequency information about the Fourier phase spectrum when averaged over multiple short-exposure images. The cross spectrum and bispectrum techniques calculate the average cross spectrum $C(\vec{f}, \Delta\vec{f})$ and bispectrum $B(\vec{f}_1, \vec{f}_2)$

Fig. 7 Computer-simulated long-exposure image of a binary star.

respectively, that are given by

$$C(\vec{f}, \Delta\vec{f}) = I(\vec{f})I^*(\vec{f} + \Delta\vec{f}) \quad (4)$$

$$B(\vec{f}_1, \vec{f}_2) = I(\vec{f}_1)I(\vec{f}_2)I^*(\vec{f}_1 + \vec{f}_2) \quad (5)$$

where the superscript * denotes complex conjugate. Although the cross spectrum is defined for all values of $\vec{f}$ and $\Delta\vec{f}$ only for values of $\Delta\vec{f}$ or $\vec{f}$ less than r_o/λ are the cross spectrum elements obtained with sufficiently high SNRs to be useful in the reconstruction process. The equivalent constraint on the bispectrum elements is that either $\vec{f}_1, \vec{f}_2$ or $\vec{f}_1 + \vec{f}_2$ must be less than r_o/λ . Once the average cross spectrum or bispectrum is calculated from a series of short-exposure images, the phase spectrum $\phi_1(\vec{f})$ of the underlying image can be calculated from their phases using one of a number of algorithms based upon the following equations:

$$\phi_1(\vec{f} + \Delta\vec{f}) = \phi_1(\vec{f}) - \phi_c(\vec{f} + \Delta\vec{f}) \quad (6)$$

for the cross spectrum and:

$$\phi_1(\vec{f}_1 + \vec{f}_2) = \phi_1(\vec{f}_1) + \phi_1(\vec{f}_2) - \phi_b(\vec{f}_1 + \vec{f}_2) \quad (7)$$

for the bispectrum. Because the phases are only known for units of 2π , phasor versions of Eqs. (6) and (7) must be used. For the cross spectrum technique, each short-exposure image must be centroided prior to calculating its cross spectrum and adding it to the total cross spectrum. The bispectrum technique is insensitive to tilt, so no centroiding is necessary; however, the bispectrum technique requires setting two image phase spectrum values to arbitrary values to initialize the phase reconstruction process. Typically, the image phase spectrum values at $\vec{f} = (0, 1)$ and $\vec{f} = (1, 0)$ are set equal to zero, which centroids the reconstructed image but does not affect its morphology.

To obtain an estimated Fourier transform $I_e(\vec{f})$ of the image from the energy and phase spectrum estimates, the square root of the average energy spectrum is combined with the average phase spectrum calculated from either the bispectrum or cross spectrum. The result is given by

$$I_e(\vec{f}) = [E_1(\vec{f})]^{1/2} \exp[j\phi_1(\vec{f})] \quad (8)$$

where $j = \sqrt{-1}$. The result in Eq. (8) includes atmospheric attenuation of the Fourier amplitudes, so it must be divided by the amplitude spectrum of the atmosphere to obtain the desired object spectrum estimate. The atmospheric amplitude spectrum estimate is obtained by using Labeyrie's technique on a sequence of short-exposure images of a nearby unresolved star. No phase spectrum correction is necessary because it has been shown theoretically and verified experimentally that atmospheric turbulence has a negligible effect upon $\phi_1(\vec{f})$.

Blind Deconvolution

Speckle imaging techniques are effective as well as easy and fast to implement. However, it is necessary to obtain a separate estimate of the atmospheric energy spectrum using an unresolved star in order to reconstruct a high-resolution image. Usually, the star is not co-located with the object and the star images are not collected simultaneously with the images of the object. As a result,

the atmospheric energy spectrum estimate may be inaccurate. At the very least, collecting the additional star data expends valuable observation time. In addition, there is often meaningful prior knowledge about the object and the data, such as the fact that measured intensities are positive (positivity), that many astronomical objects are imaged against a black background (support), and that the measured data are band-limited, among others. Speckle imaging algorithms do not exploit this additional information. As a result, a number of techniques have been developed to jointly estimate the atmospheric blurring effects as well as an estimate of the object being imaged using only the short-exposure images of the object and available prior knowledge. These techniques are called blind deconvolution techniques. Two of the most common techniques are known as multi-frame blind deconvolution (MFBD) and projection-based blind deconvolution (PBBD).

The MFBD algorithm is based upon maximizing a figure of merit to determine the best object and atmospheric short-exposure point spread function (PSF) estimates given the data and available prior knowledge. This figure of merit is created using a maximum likelihood problem formulation. Conceptually, this technique produces estimates of the object and the atmospheric turbulence short-exposure PSFs that most likely generated the measured short-exposure images. Mathematically, the MFBD algorithm obtains these estimates by maximizing the conditional probability density function (pdf) $p[i_m(\vec{x})|_o(\vec{x}); h_m(\vec{x}), m = 1, \dots, M]$, where $i_m(\vec{x})$ is the m th of M short exposure images and is given by

$$i_m(\vec{x}) = h_m(\vec{x}) * o(\vec{x}) + n_m(\vec{x}) \quad (9)$$

where $h_m(\vec{x})$ and $n_m(\vec{x})$ are the atmospheric/system blur and detector noise functions for the m th image, respectively, and the asterisk denotes convolution. The noise is assumed to be zero mean with variance $\sigma^2(\vec{x})$. The conditional pdf $p[i_m(\vec{x})|_o(\vec{x}); h_m(\vec{x}), m = 1, \dots, M]$ is the pdf of the noise with a mean equal to $h_m(\vec{x}) * o(\vec{x})$ and, as a function of $o(\vec{x})$ and $h_m(\vec{x})$, it is known as a likelihood function. For spatially independent Gaussian noise, as is the case for camera read noise, the likelihood function is given by

$$L_G[o(\vec{x}); h_m(\vec{x}), m = 1, \dots, M] = \prod_m \prod_{\vec{x}} \frac{1}{\sqrt{2\pi\sigma^2(\vec{x})}} \exp\left\{-[i(\vec{x}) - (o * h_m)(\vec{x})]^2 / 2\sigma^2(\vec{x})\right\} \quad (10)$$

For Poisson noise, the likelihood function is given by

$$L_P[o(\vec{x}); h_m(\vec{x}), m = 1, \dots, M] = \prod_m \prod_{\vec{x}} \frac{[(o * h_m)(\vec{x})]^{i(\vec{x})} \exp\{-(o * h_m)(\vec{x})\}}{i(\vec{x})!} \quad (11)$$

In practice, logarithms of Eqs. (10) and (11) are taken prior to searching for the estimates of $o(\vec{x})$ and $h_m(\vec{x})$ that maximize the likelihood function.

In general, there are an infinite number of estimates of $o(\vec{x})$ and $h_m(\vec{x})$ that reproduce the original dataset when convolved together. However, when additional prior knowledge is included to constrain the solution space, such as positivity, support, and the knowledge that $h_m(\vec{x})$ is band-limited, along with regularization, the MFBD algorithm almost always converges to the correct estimates of $o(\vec{x})$ and $h_m(\vec{x})$.

The PBBD technique also uses prior knowledge constraints to jointly estimate $o(\vec{x})$ and $h_m(\vec{x})$. However, instead of creating and maximizing a likelihood function, the PBBD technique uses the method of convex projections to find estimates of $o(\vec{x})$ and $h_m(\vec{x})$ that are consistent with the measured short-exposure images and all the prior knowledge constraints. The data consistency constraint and the prior knowledge constraints are mathematically formulated as convex sets and the PBBD technique repeatedly takes the current estimates of $o(\vec{x})$ and $h_m(\vec{x})$ and projects them onto the convex constraint sets. As long as all the sets are truly convex, the algorithm is guaranteed to converge to a solution that is in the intersection of all the sets as long as the algorithm doesn't stagnate at erroneous solutions called traps. These traps are the projection equivalent of local minima in cost function minimization algorithms.

A key component of this algorithm is the ability to formulate the measured short-exposure images and prior knowledge constraints into convex sets. As an example, consider the convex set $C_{\text{pos}}[u(\vec{x})]$ that corresponds to the positivity constraint. This set is given by

$$C_{\text{pos}}[u(\vec{x})] \triangleq \{u(\vec{x}) \text{ such that } u(\vec{x}) \geq 0\} \quad (12)$$

It is straightforward to show that $C_{\text{pos}}[u(\vec{x})]$ is a convex set. Other constraints can be converted into convex sets in a similar manner. Although all constraints can be formulated into sets, most but not all of these sets are convex.

The projection process is straightforward to implement. For example, the projections of the current estimates of $o(\vec{x})$ and $h_m(\vec{x})$ onto $C_{\text{pos}}[u(\vec{x})]$ are carried out by zeroing out the negative values in these estimates. Similarly, the projections of $o(\vec{x})$ and $h_m(\vec{x})$ onto the convex sets that correspond to their support constraints are carried out by zeroing out all their values outside of their supports. In practice, some versions of PBBD algorithms have been formulated to use minimization routines as part of the projection process in order to minimize the possibility of stagnation.

Deconvolution from Wavefront Sensing

A key distinguishing feature of post-detection compensation algorithms is the type of additional data required to estimate and remove atmospheric blurring in the measured short-exposure images. Blind deconvolution techniques need no additional data. Speckle imaging techniques estimate average atmospheric blurring quantities and need an estimate of the average atmospheric

energy spectrum. Because average quantities are calculated when using speckle imaging techniques, only an estimate of the average atmospheric energy spectrum is needed, not the specific energy spectra that corrupted the measured short-exposure images. As a result, the additional data need not be collected simultaneously with the short-exposure images. The technique described in this section, deconvolution from wavefront sensing (DWFS), seeks to deconvolve the atmospheric blurring in each short-exposure image by estimating the specific atmospheric field phase perturbations that blur each short-exposure image. Thus, the additional data must be collected simultaneously with the short-exposure images. The atmospheric field phase perturbations are calculated from data obtained with a wavefront sensor using a different region of the optical spectrum than used for imaging so that no light is taken from the imaging sensor. Most commonly, the wavefront sensor data consists of the first derivatives of the phasefront (phase differences) as obtained with Shack–Hartmann or shearing interferometer wavefront sensors, but curvature sensing wavefront sensors are also used that produce data that are proportional to the second derivatives of the phasefront.

The original algorithm to implement the DWFS technique produced an estimate $\hat{O}(\vec{f})$ of the Fourier transform $O(\vec{f})$ of the object being imaged using the following estimator:

$$\hat{O}(\vec{f}) = \frac{\sum_m I_m(\vec{f}) \tilde{H}_m^*(\vec{f})}{\sum_m |\tilde{H}_m(\vec{f})|^2} \quad (13)$$

where $\tilde{H}_m(\vec{f})$ is the overall system transfer function (including the telescope and atmospheric effects) for the m th short-exposure image estimated from the wavefront sensor data. To create $\tilde{H}_m(\vec{f})$ the atmospheric field phase perturbations corrupting the m th image must be calculated from the wavefront sensor measurements. Then $\tilde{H}_m(\vec{f})$ is obtained using standard Fourier optics techniques. Although Eq. (13) is easily implemented given an existing system that includes a wavefront sensor, it suffers from the fact that it is a biased estimator. An unbiased version of Eq. (13) is given by

$$\hat{O}(\vec{f}) = \frac{\sum_m I_m(\vec{f}) \tilde{H}_m^*(\vec{f})}{\sum_n H_{n,\text{ref}}(\vec{f}) \tilde{H}_{n,\text{ref}}^*(\vec{f})} \quad (14)$$

where $\tilde{H}_{n,\text{ref}}(\vec{f})$ and $\tilde{H}_{n,\text{ref}}^*(\vec{f})$ are estimates of the overall system transfer function obtained from data collected on a reference star using wavefront sensor data and image-plane data, respectively. Thus, to obtain an unbiased estimator, two more datasets must be collected. The number of frames in the reference star dataset need not be the same as for the imaging dataset. As for speckle imaging, the atmospheric statistics must be the same for the reference star and imaging datasets.

Another technique that uses at least one additional data channel along with the measured image is called phase diversity. In the additional data channels, images are also recorded, but with known field phase aberrations intentionally introduced to add known diversity to the unknown field phase corrupting the measurements. The most commonly introduced field phases aberration in an additional channel is defocus due to its ease of implementation. In the case of defocus, the additional data channel along with the imaging channel can be viewed as samples of the focal volume of the imaging system. Both the noise-free object and the unknown field phase aberrations can be recovered from the measured data using optimization techniques to enforce data consistency along with other prior knowledge constraints. These types of systems can use higher-order aberrations as well. The phase diversity concept has been generalized to an approach known as computational imaging, where an imaging system is designed by taking into account its intended use, the expected image degradation mechanisms, and the fact that the image will be the product of both an optical system and a postprocessing algorithm.

Pre-Detection Compensation

The primary pre-detection-only compensation technique in use today employs dynamical electro-optical systems to sense and remove the phases in the impinging wavefront due to atmospheric turbulence. This technique, known as adaptive optics, provides much higher-quality data than post-detection compensation techniques, when there is enough light from the object being imaged or a guidestar (artificial or natural) to drive the adaptive optics system at a bandwidth high enough to keep up with the temporal changes in atmospheric turbulence. It consists of a wavefront sensor that measures the portion of the phasefront in the pupil of the telescope that is due to atmospheric turbulence, a wavefront reconstructor that generates the deformable mirror drive signals from the wavefront sensor data, and a deformable mirror that applies the conjugate of the atmospheric phase distortions to a reimaged pupil. Some of the light reflected off the deformable mirror is then sent to the imaging sensor. Here, it suffices to say that no adaptive optics system produces imagery that is diffraction limited in quality, although, under the right conditions, the images can be near diffraction limited. However, atmospheric seeing conditions fluctuate significantly over a night as well as seasonally. Therefore, virtually all adaptive optics images benefit from applying post-compensation techniques, as is discussed next.

Hybrid Techniques

Adaptive Optics and Post-Processing

Often, an adaptive optics system does not fully correct for atmospheric turbulence. This can occur when atmospheric conditions become worse than the system is designed to handle. Also, an adaptive optics system may be intentionally designed to only

partially correct for atmospheric turbulence in order to lower the cost of the system. As a result, there still may be significant atmospheric blurring in systems that use adaptive optics. For this reason, additional post-processing of adaptive optics imagery can result in significant improvement in image quality. All of the techniques discussed in the section on post-detection compensation can be applied to adaptive optics imagery. Applying these techniques should never degrade image quality, and will improve the quality if the adaptive optics system doesn't fully correct for atmospheric turbulence. Generally speaking, the amount of improvement decreases as the performance of the adaptive optics system increases. Because the adaptive optics system's performance parameters can vary as atmospheric conditions vary, the blind deconvolution algorithms are especially applicable to processing adaptive optics imagery since they estimate the overall system transfer function from the imaging data. Because speckle imaging techniques require a separate estimate of the overall system transfer function, it can be difficult and time-consuming to obtain all of the additional data necessary to apply these techniques to adaptive optics data. Since these post-detection compensation techniques require short-exposure images, the adaptive optics system needs to have a camera capable of collecting short-exposure images. Finally, even if an adaptive optics system fully corrects for the atmosphere, deconvolution techniques that remove the diffraction-limited transfer function amplitude attenuation can improve image quality.

Partially Redundant Pupil Masking

Although adaptive optics systems can function very well, currently they are expensive and require significant maintenance. The primary benefit of adaptive optics systems is that they remove atmospheric turbulence phase distortions in the pupil of the telescope, thus permitting light from all areas of the pupil to interfere in phase when creating an image. An interferometric view of imaging reveals that multiple regions of the light in the pupil contribute to a single spatial frequency in the image. When the phasefront in the pupil is distorted by the atmosphere, these multiple regions tend to not interfere in phase, reducing the amplitude of the image's Fourier component at that spatial frequency. This amplitude reduction effect occurs for all spatial frequencies greater than the limit imposed by the atmosphere, r_o/λ . Therefore, techniques have been developed to modify the wavefront by masking part of the pupil prior to measuring the field with an imaging sensor. This class of techniques has various names including optical aperture synthesis, pupil masking, and aperture masking. Here this class of techniques will be referred to as partially redundant pupil masking (PRPM).

PRPM techniques function by masking the pupil in such a way as to minimize the amount of out-of-phase interference of light on the imaging detector. Early efforts used pupil masks that were opaque plates with r_o -sized holes in them. Because the atmospheric coherence length is r_o , all the light from an r_o -sized hole is essentially in phase. By choosing the holes in the mask so that only two holes contribute to a single spatial frequency in the image, out-of-phase interference problems are removed. This type of mask is called a nonredundant pupil mask. Of course, a significant amount of light is lost due to this masking, so only bright objects benefit from this particular implementation. Often, the pupil mask needs to be rotated in order to obtain enough spatial frequencies in the image to be able to reconstruct a high-quality estimate of the object. To increase the light levels in the image, masks have been made to allow some out-of-phase interference for a given spatial frequency, thus trading off the amplitude of the spatial frequencies allowed in the image with the amount of light in the image. Masks with this property are called partially redundant pupil masks.

One version of PRPM is called the variable geometry pupil (VGP) technique. It is envisioned to work in conjunction with an adaptive optics system that does not fully correct the wavefront for atmospheric phase distortions. It employs a spatial light modulator or a micro-electromechanical mirror between the deformable mirror and the imaging sensor. Either of these two devices is driven by signals from the wavefront sensor in the adaptive optics system in such a way that the portions of the pupil where the phasefront has a sufficiently large second derivative is blocked, while the remainder of the phasefront is transmitted.

All PRPM techniques benefit from post-compensation processing. For the case of nonredundant pupil masks, post-processing techniques are required to convert the discrete-spatial-frequency information into an image with reasonable quality. These techniques are essentially the same techniques as used in interferometric imaging, not those described in this article. When partially redundant pupil masks are used (including VGP masks), the image may include enough spatial frequency content that the methods described in the post-detection compensation section can be applied.

Bob D. Guenther received his undergraduate degree from Baylor University and his graduate degrees in Physics from University of Missouri. He has had research experience in condensed matter and optical physics. For 9 years he was active in research management as a Senior Executive in the Army, responsible for the physics research sponsored by the Army. After retiring from the government he held the position of Interim Director of the Free Electron Laser Laboratory and helped establish Duke's Fitzpatrick Center for Photonics and Communication Systems and served as Executive Director of the Center until his retirement. In a continuation of the retirement process, he moved to Applied Quantum Technology and has just retired from that company. He is author of the textbook, *Modern Optics*, second edition. He is now composing an elementary book in optics.

Duncan G. Steel is the Robert J. Hiller Professor of Electrical and Computer Engineering, as well as Professor of Physics and Biophysics. Prior to joining the faculty of the University of Michigan in 1985, he was a senior research scientist at Hughes Aircraft Company at the Hughes Research Laboratories. At the University of Michigan, he was Area Chair and Director of the Optical Sciences Laboratory for 20 years until 2007 when he took over the position of Chair of the Biophysics Research Division during its transition to an academic unit. As an educator and teacher, he has chaired or cochaired over 60 doctoral committees. His research includes coherent optical studies of semiconductors and their application to quantum information. His work also included 30 years of studies on age-related modifications in proteins where he exploited numerous optical techniques including single molecule studies in neurons in his studies on Alzheimer's Disease. He was a Guggenheim Scholar and received the 2010 Isakson Prize from the American Physical Society.

INTRODUCTION

This is the second, updated edition of the *Encyclopedia of Modern Optics*. There are 197 entries, many of them new or updated, reflecting the enormous progress in the optical sciences and technology and the ever-expanding impact since the publication of the first edition. Some of the new topics are:

- Nano-photonics and Plasmonics
- Quantum Optics
- Quantum Information
- Optical Interconnects
- Photonic Crystals and Their Applications
- High Efficiency LED's
- Displays
- Transformation Optics
- Fiber Lasers
- Terahertz
- Multidimensional Spectroscopy
- Organic Optoelectronics
- Gravitational Wave Detectors
- Meta Materials and Plasmonics

Selection of article topics and recruiting authors for those topics in this edition has been the work of the topical editors listed in the prologue. They were able to solicit contributions from internationally recognized leaders in their field.

The entries of the encyclopedia are arranged by subject as best as possible, a task made difficult because the field is now highly interdisciplinary and there are many subjects that have an impact in many different areas. We have added references to other articles so that readers can obtain a deeper understanding of the material or understand how a specific discussion on basic science may impact an application or technology.

Basic Concepts of Optical Communication Systems

Introduction

Since modern lightwave communication started in the 1970s, extensive efforts have been made to increase data rate and transmission distance. Recently, the bit rates for single-channel and multichannel systems have exceeded 40 and 2 Tb/s on single fibers respectively, for transoceanic distances. One revolutionary development in lightwave systems has been the deployment of erbium doped fiber amplifiers (EDFAs). These amplifiers facilitate transmission of an optical signal over long distances, by providing periodic analog-like amplification rather than digital-like regeneration. The wide bandwidth provided by EDFAs has made possible the increased use of wavelength division multiplexing (WDM) in which multiple lightwave signals, each having a different wavelength, are co-propagated on a single fiber. EDFAs and WDM techniques can enhance the lightwave system capacity, both in terms of obtainable transmission distance, and total number of data rates (see Fig. 1).

Optical Fiber

Most telecommunication fibers are made of silica, therefore following the attenuation of silica material. Fig. 2 shows the silica fiber attenuation as a function of wavelength. The downward slope towards 1.6 μm and upward slope away from 1.6 μm , are the theoretical limits due to Rayleigh scattering and absorption of silica material, respectively. The absorption peak near 1.4 μm is due to water molecule absorption. There are two low attenuation regions: $\sim 1.3 \mu\text{m}$ and 1.55 μm , both of which are used for communications in general, and some other wavelengths are also used for shorter distance communications. Fig. 2 also shows the comparison between gain bandwidth of EDFA ($\sim 3 \text{ THz}$) and the low attenuation window around 1.55 μm ($\sim 25 \text{ THz}$). The typical values of attenuation at 1.3 μm and 1.55 μm for single-mode fiber (SMF) are $\sim 0.35 \text{ dB/km}$, and 0.2 dB/km , respectively.

When an electromagnetic wave interacts with the bound electrons of a silica fiber, the medium response depends upon optical frequency (ω). This property, referred to as material dispersion, manifests itself through the frequency dependence of the refractive

Fig. 1 Bit rate product. Data from T. Li (private communication).

Fig. 2 Silica fiber attenuation versus wavelength.

index $n(\omega)$. Fiber material dispersion plays a critical role in propagation of short optical pulses since different spectral components associated with the pulse travel at different speeds, given by $c/n(\omega)$. Consequently, the optical pulse at the output of the fiber is broadened in time. The commonly used system parameter is called the dispersion parameter D (the negative D value is called normal dispersion, and the positive D value is called anomalous dispersion), and is measured in $\text{ps}/(\text{nm} \cdot \text{km})$; D for SMF is $\sim +17 \text{ ps}/(\text{nm} \cdot \text{km})$ at $1.5 \mu\text{m}$. However, because of dielectric waveguiding, the effective mode index is slightly lower than the material index $n(\omega)$, with the reduction itself being ω -dependent (waveguide dispersion). This results in a waveguide contribution that must be added to the material contribution to obtain the total dispersion (see Fig. 3).

Generally, the waveguide contribution to dispersion D is to shift zero dispersion wavelength (λ_0) to longer wavelengths. Furthermore, the waveguiding can be tailored to shift the λ_0 from $1.3 \mu\text{m}$ to $1.5 \mu\text{m}$, the wavelength at which the fiber has the minimum attenuation loss. The fiber having λ_0 in the neighborhood of $1.5 \mu\text{m}$, is called dispersion-shifted fiber (DSF); D for DSF is usually between -2.5 and $+2.5 \text{ ps}/\text{nm} \cdot \text{km}$, at a wavelength of $1.5 \mu\text{m}$. The typical dispersion parameter, D , as a function of a wavelength for both SMF and DSF, is shown in Fig. 4.

In addition to chromatic dispersion, optical fiber has another dispersion properties related to polarization. An optical wave of arbitrary polarization can be represented as the superposition of two orthogonally polarized modes. In an ideal fiber, these two modes are indistinguishable, and have the same propagation constants owing to the cylindrical symmetry of the waveguide. However, in real fibers there is some residual anisotropy due to unintentional circular asymmetry, usually caused by noncircular waveguide geometry or asymmetrical stress around the core, as shown in Fig. 5.

In either case, the loss of circular symmetry gives rise to two distinct orthogonally-polarized modes with different propagation constants (differential phase velocity) responsible for polarization mode dispersion (PMD) in the fiber, and can be related to the difference in refractive indices (birefringence) between the two orthogonal polarization axes. The differential phase velocity indicated is accompanied by a difference in the group velocities for the two polarization modes, therefore the pulse at the end of

Fig. 5 Origin of PMD.

the transmission fiber is broadened by this differential group delay (DGD). DGD is usually expressed in units of ps/km for a short length (1 m to 1 km) of birefringent fiber. However, DGD does not accumulate along a long fiber link in a linear fashion. Instead, because of random variations in the perturbations along a fiber span, the DGD in one section may either add to or subtract from another section of the fiber. As a result, average DGD in long fiber spans accumulates in a random-walk-like process that leads to a square root of transmission-length dependence. Therefore, average DGD is expressed in ps/km^{1/2} in long fiber spans, referred to as the PMD of the fiber, and the typical PMD parameter has a value of 0.01 to 10 ps/km^{1/2}. Because of the many perturbations that act on a real-world fiber (e.g., temperature, vibration, etc.), transmission properties typically vary with time. Therefore, the PMD of the fiber link fluctuates randomly, thus causing random fluctuations in system performance.

It is well known that optical fibers show nonlinear behavior under conditions of high power and long interaction length. The power-times-distance products for amplified transmission systems can be large enough to make fiber nonlinear effects the dominant factor in the design of long-distance systems.

There are two categories of fundamental optical nonlinear effects: stimulated scattering effects and refractive index effects. Stimulated scattering effects arise from parametric interactions between light and acoustic or optical phonons in the fiber. Two nonlinear effects fall into this category: stimulated Brillouin scattering (SBS) and stimulated Raman scattering (SRS). The main difference between the two is that optical phonons participate in SRS, while acoustic phonons participate in SBS. In a simple quantum-mechanical picture, a photon of the incident field is annihilated to create a photon at a longer wavelength. The new photon is co-propagated and counter-propagated along the original signal in SRS, while counter-propagated in SBS. Refractive index effects are caused by modulation due to changes in light intensity. There are three types of refractive index effects: self-phase modulation (SPM), cross-phase modulation (XPM), and four-wave mixing (FWM). SPM introduces the change of optical phase by its own intensity, and, this leads to frequency chirp of the pulse, depending on the relative position from the peak. When this nonlinear frequency chirp interacts with the fiber dispersion, the pulse either broadens or compresses, depending on the sign and the amount of dispersion along the fiber. In XPM, the phase of the signal in one wavelength channel is modulated by the intensity fluctuation of the other wavelength channels. In a WDM system, XPM imposes far more damaging effects than SPM because XPM is stronger by a factor of two than SPM when the channel power is the same, and large number of WDM channels can contribute to XPM. FWM is the generation of modulation sideband at new frequencies, due to the phase modulation of channels between lights at different frequencies in multichannel system. FWM causes penalties in a WDM system if the newly generated frequency is either equal to or close to the frequency of existing WDM channels.

Fiber nonlinearities impose significant degradation in optical transmission system, and limit the system on allowable number of channels, channel power, and channel spacing (see Fig. 6). But, the effects can be well suppressed by carefully designing the fiber dispersion profile (i.e., dispersion map) in the transmission system, and controlling the optical launch power for each fiber span.

Communication Components

Distributed feedback laser (DFB) is widely used as a light source for metro, long-haul, and undersea applications, due to its narrow spectral width, and wavelength stability. Fabry–Perot (FP) lasers, and vertical cavity surface emitting lasers (VCSEL) are used for local area networks (LAN), and for access applications, because these are cheaper than DFB lasers. For an application, where the cost is the most important parameter with low data modulation speed, light-emitting diode (LED) is used as a light source.

In optical data modulation, the simplest and easiest technique is turning ON or OFF the laser, depending on the binary logic '1' or '0' (direct modulation). This type of modulation is simple and cheap compared to external modulation technique. But, its application is limited by the bandwidth of modulation, and the induced frequency chirp (i.e., difference in optical frequency at the turn ON state and just before the turn OFF state of laser) that limits the transmission distance. Two different types of external modulators are widely used for digital optical data transmission. Electro absorption modulator (EAM) uses the Franz–Keldysh effect, where it is observed that the wavelength of the optical absorption edge in a semiconductor is lengthened by applying an electric field. Electro-optic modulator (EOM) utilizes the linear electro-optic effect, called the Pockels effect, which changes the refractive index of the material caused by and proportional to an applied electric field, so therefore changes the phase of the optical signal. This phase change is used to modulate the intensity of a lightwave through a Mach–Zehnder (MZ) interferometer (see Fig. 7). Because the Pockels effect exists only in crystal, lithium niobate crystal (LiNbO₂) or electro-optic polymers are used for EOM.

EDFA is a wideband optical amplifier that has merits in that: (i) erbium ions (Er^{3+}) emit light in the $1.55 \mu\text{m}$ loss-minimum band of optical fiber, (ii) a circular fiber-based amplifier is inherently compatible with a fiber optics system; (iii) it provides amplification independent of bit-rate, modulation format, power, and wavelength; and (iv) it has low distortion and low noise during amplification. EDFA contains a gain medium (i.e., erbium-doped fiber) that must be inverted by a pump source. A signal initiates stimulated emission, resulting in gain, and spontaneous emission occurs naturally, which results in noise.

Fig. 8 shows the energy level and transition diagram of EDFA. A $0.98 \mu\text{m}$ pump photon is absorbed and excites a carrier (Er^{3+} ions) into higher excited states, and the excited carrier decays rapidly to the first excited state that has a very long lifetime of $\sim 10 \text{ ms}$ (metastable state). In contrast, a $1.48 \mu\text{m}$ pump photon is absorbed and excites a carrier into a metastable state.

This long metastable state is one of the key advantages of EDFA, and intersymbol distortion and interchannel crosstalk are negligible as a result of these slow dynamics. Depending on the external optical excitation signal, this carrier will decay in a stimulated or spontaneous fashion to the ground state and emit a photon. Both absorption and emission spectra have an associated bandwidth depending on the spread in wavelengths that can be absorbed or emitted from a given energy level. This is highly desirable because (i) a pump laser does not need to be an exact wavelength; and (ii) the signal may be at one of several wavelengths, especially in a WDM system. Fig. 9 shows the bandwidth in the 1.48 μm absorption and 1.55 μm fluorescence spectrum of a typical erbium-doped amplifier.

When the noise characteristics of EDFA are considered, noise figure (NF) is an important parameter, which is defined by $NF \equiv SNR_{in}/SNR_{out}$, where SNR_{in} (SNR_{out}) is the electrical equivalent signal-to-noise ratio (SNR) of the optical wave going into (coming out) of the amplifier, if it were to be detected. The typical value of NF in commercially-available EDFA is 4.5–6 dB. The importance of NF in optical communication systems is presented later in this chapter, when the required optical SNR (OSNR) for error-free optical data transmission is considered. Fig. 10 shows an example of EDFA diagram.

Recent development of EDFA in longer wavelength regimes or L-band (1570–1620 nm) has doubled the useful transmission bandwidth over the conventional band or C-band (1525–1265 nm). L-band gain of EDFA is generally achieved by proper arrangement of pump lasers through longer lengths of erbium-doped fiber than conventional C-band EDFA. Fig. 11(a) shows the concept of wideband EDFA. The incoming WDM signal is split into two bands (C- and L-bands), amplified separately, and combined at the output. Gain and NF characteristics of this wideband EDFA is shown at Fig. 11(b).

Fig. 12 Block diagram of functions performed in advanced receiver packages.

Because SRS transfers the energy of a lower wavelength channel into the higher wavelength channel in the optical fiber, the transmission fiber itself can be used as a gain medium on specific channel (or channels) when the proper pump signal (or signals) are provided in the fiber. Even though Raman gain is much lower than the gain of EDFA (i.e., < 0.1 dB gain/mW pump in Raman amplifier (RA) compared to a few dB gain/mW pump in EDFA), RA has several advantages over EDFA (i) RA has the capability to provide gain at any signal wavelengths, (ii) the amplification window is expandable by combining multipump wavelengths; and (iii) RA offers improved noise performance because the signal is amplified over transmission fiber (i.e., distributed amplifier). Especially improved noise performance increases system OSNR, which can be used to extend system reach or create more wavelength channels on the system. The Raman pumps are typically located ~ 100 nm shorter than the wavelength of the signal to be amplified, and a few 100s mW pump lasers are used to get a 10–15 dB gain.

In general, telecom receiver (RCVR) consists of photo diode (PD) with transimpedance amplifier (TIA), followed by limiting amplifier (LA) or automatic gain control amplifier (AGC), low pass filter, and clock data recovery circuit (CDR) (see Fig. 12).

Vertically illuminated positive-intrinsic-negative (PIN) photodiode and avalanche photo diode (APD) are the most common PD that is used in RCVR. In PIN, incoming light is absorbed in the n^- (low doped or intrinsic) region and generates an electron-hole pair, which drifts to a depletion region and collected n^+ and p^+ regions, therefore generating electric current. APD is used for high-sensitivity detection up to 10 Gb/s. It is structured as absorption, grading, and multiplication layers. The multiplication layer of APD provides additional transit time delay compared to PIN, therefore the bandwidth of APD is smaller than PIN in general. TIA is a broadband low noise amplifier that is used to convert and amplify the weak current from PD to the desired output voltage. A low pass filter is used to suppress the noise and data distortion from high frequency components with a typical cut-off frequency ~ 0.7 bitrate. LA and AGC are amplifiers that limit the output voltage as a constant. LA is a nonlinear amplifier that makes a decision either to make logic '1' or '0' based on input voltage level, and limits output voltage as fixed values. AGC is a linear amplifier that limits the output voltage by adjusting the gain of the amplifier based on input voltage level. CDR consists of a phase lock loop (PLL) with a voltage controlled oscillator (VCO) and data flip-flop circuit. The PLL is used to synchronize the VCO to the incoming high-speed bit stream, therefore recovering the system clock. The recovered clock is used in D-FF to retiming and regenerate the data.

Data Modulation Formats

In digital optical communications, numerous modulation formats have been developed and utilized, in order to achieve higher spectral efficiency (i.e., ratio of individual channel bit rate to dense WDM (DWDM) separation), and to improve system performance over fiber impairments. A simple amplitude modulation of lightwave is still the most widely used method for optical communication. The easiest amplitude modulation technique is to using a nonreturn-to-zero (NRZ) format. Fig. 13(a) shows an example of NRZ binary sequence in time domain, and the corresponding frequency domain spectrum. In NRZ, data '1' and '0' correspond to the ON and OFF state of a lightwave transmitter, respectively, occupying entire bit time (i.e., binary symbol time). When the ON or OFF state of a lightwave transmitter does not occupy the entire bit time (T_B) (i.e., when the data pulse duration (T_d) is less than (T_B) it is called the return-to-zero (RZ). Fig. 13(b) shows a binary sequence of RZ, and its frequency spectrum when $T_d \approx 0.5T_B$. The Fourier transform of the square wave is the Sinc function. Therefore, the frequency spectrum of an ideal NRZ and RZ follows the pattern of a Sinc square function. Note that the first null of frequency spectrum of RZ is about twice as high as the null of NRZ.

Even though NRZ is better in spectral efficiency than RZ, RZ has an advantage over NRZ in tolerance of fiber impairments. Fig. 14 shows an example on eye closure penalty comparison between NRZ and RZ data formats at a 16-channel WDM system at 40 Gb/s data rate. It is clearly seen that the penalty of RZ is much less severe than the penalty of NRZ, as the transmission distance increases. (Note, nonlinearities and dispersion increases as the transmission distance increases.)

There has been much effort to increase the spectral efficiency, to improve the system performance over fiber impairments, or to achieve both simultaneously. Fig. 15 shows some of examples of these. Chirped RZ (CRZ) is the modulation format inducing frequency chirp on conventional RZ. CRZ is robust on fiber impairment at the cost of losing spectral efficiency. In carrier-suppressed RZ (CS-RZ), a strong un-modulated optical carrier is removed from conventional RZ, therefore suppressing the nonlinear effects. Duo-binary is a three-level signal modulation format generated by a series of delay and added circuits in the

Fig. 13 Amplitude modulation (a) nonreturn-to-zero (NRZ), and (b) return-to-zero (RZ).

Fig. 14 System performance of different modulation format (NRZ vs. RZ).

transmitter. The advantage of duo-binary is that its bandwidth is reduced to one half of conventional NRZ, therefore having enhanced spectral efficiency, and has a high tolerance in chromatic dispersion, and suppression of fiber nonlinearities.

Single-sideband (SSB) or vestigial singleside band (VSB) can be generated into either NRZ or RZ, by either optically utilizing optical filtering with a sharp cut-off filter, or electrically applying tapped-delay-line filter approximation on both amplitude and phase modulators. SSB (or VSB) has about a two times higher spectral efficiency and higher tolerance on chromatic dispersion than conventional modulation formats.

Data Multiplexing

At their most basic, optical networks can imitate electrical networks in which time division multiplexing (TDM) is overwhelmingly used for digital data transmission. A fiber can carry many time-multiplexed channels, in which each channel can transmit its data in an assigned time slot. A typical TDM link is shown in **Fig. 16**, in which N transmitters are sequentially polled by a fast multiplexer to transmit their data. The time-multiplexed data are sequentially and rapidly demultiplexed at the receiving node.

Time multiplexing and demultiplexing functions can be performed either electrically with an electrical time (DE)MUX switch and an optical transmitter/receiver, or optically with multiple optical transmitters/receivers and an optical time (DE)MUX switch. The major advantage of TDM is that there is no output-port contention problem (each data bit occupies its own time slot and there is only a single high-speed signal present at any given instant). The disadvantage of TDM is that the scheme requires a ultra-high-speed switching component if the individual signals are themselves high-speed and if there are many users.

In WDM, multiple wavelength channels are transmitted through a single fiber, therefore enabling the fiber to carry more throughput. By using wavelength-selective devices for the ON and OFF ramps, independent signal routing also can be accomplished. **Fig. 17(a)** shows a simple point-to-point WDM system in which several channels are multiplexed at one node, the combined signals transmitted across a distance of fiber, and the channels demultiplexed at a destination node. As shown in

Fig. 15 Examples of bandwidth efficient modulation formats. (a) Chirped RZ (CRZ) generation, (b) carrier suppressed-RZ (CS-RZ) generation, (c) duo-binary generation, and (d) vestigial single side band (VSB) RZ generation.

Fig. 16 Concept of bit-interleaving TDM.

Fig. 17(b), the wavelength becomes the signature address for either the transmitter or the receivers, and the wavelength will determine the routing path through an optical network.

Many interesting challenges face the eventual implementation of WDM systems and networks. Several of these challenges involve the control and management of the data through this novel high-speed network. **Fig. 18** shows a small subset of critical component technologies typically required for a WDM system, including multiple-wavelength transmitters, multiport star couplers, passive and active wavelength routers, EDFAs, and tunable optical filters.

Some generic goals that a WDM-device technologist aims to achieve include; large wavelength tuning range; multi-user capability; wavelength selectivity and repeatability; low cross-talk; high extinction ratio; minimum excess losses; fast wavelength tunability; high-speed modulation bandwidth; low residual chirp; high finesse; low noise; robustness; high yield; potential low cost. Depending on system requirements, device availability and cost, WDM technologies divide into two; course-WDM (CWDM) and dense-WDM DWDM. **Fig. 19** shows the wavelength allocation for CWDM and DWDM. CWDM technology uses an International Telecommunication Union (ITU) standard 20 nm spacing between the wavelengths from 1310 nm to 1610 nm. Also DWDM technology uses an ITU standard 100 GHz or 200 GHz between wavelengths, arranged in several bands at around 1500–1600 nm.

Fig. 17 (a) A simple point-to-point WDM transmission system; (b) a generic multiuser network in which the communication links and routing paths are determined by the wavelengths used within the optical switching fabric.

Fig. 18 Schematic of a small subset of enabling device technologies for a WDM system.

Fig. 19 WDM wavelength allocation.

Dispersion Management and Compensation

As mentioned previously, chromatic dispersion is one of the most basic characteristics of fiber, although it is possible to manufacture fiber that induces zero chromatic dispersion. But such fiber is incompatible with the deployment of a WDM system since harmful nonlinear effects are generated, therefore chromatic dispersion must exist, and must be compensated for. The effect of chromatic dispersion is cumulative and increases quadratically with the data rate (see Fig. 20).

The quadratic dependence of dispersion with the data rate is a result of two effects. First, a doubling of the data rate will double the Fourier-transformed frequency spectrum of the signal, thereby doubling the effect of dispersion. Second, the same doubling of the data rate makes the data pulse only half as long in time and therefore twice as sensitive to temporal spreading due to dispersion. The conventional wisdom for the maximum distance over which data can be transmitted is to consider a broadening of

Fig. 20 Pulse broadening at two different data rates (2.5 Gbit/s, and 10 Gbit/s) as a result of quadratic nature of chromatic dispersion.

Fig. 21 Dispersion-limited (uncompensated) transmission distance in single-mode fiber (SMF) as a function of data rate for intensity-modulated optical signals. Courtesy of L.D. Garrett.

Fig. 22 Typical static management of chromatic dispersion.

the pulse equal to the bit time period. For a bit period B a dispersion value D and a spectral width $\Delta\lambda$ the dispersion-limited distance is given by $L_D = 1/(D \cdot B \cdot \Delta\lambda)$ (see Fig. 21).

In theory, compensation of chromatic dispersion for high-speed or long-distance systems can be fixed in value if each link's dispersion value is known. A simple yet elegant solution is to create a dispersion 'map', in which the designer of a transmission link alternates elements that produce positive and then negative dispersion (see Fig. 22). This is a very powerful concept: at each point along the fiber the dispersion has some nonzero value, effectively eliminating FWM and XPM, but the total accumulated dispersion at the end of the fiber link is zero, so that minimal pulse broadening is induced. The specific system design, as to the periodicity of management, depends on several variables, but a typical number for SMF as the embedded base is a compensation at every 80 km in a 10 Gb/s system. Dispersion-compensating fiber (DCF) has been generally used as a dispersion compensating element.

However, there are several important aspects of optical systems and networks that make tunable dispersion compensation solutions attractive, including: (i) it significantly reduces the inventory of different required types of compensation modules; (ii) it tunes to adapt to routing path changes in a reconfigurable network, (iii) it tracks dynamic changes in dispersion due to environment, and (iv) it achieves a high degree of accuracy necessary for 40 Gb/s channels (see Fig. 23).

Fig. 23 Effect of tunable compensation at 40 Gb/s (OC-768); it allows a wide range of transmission distance. On the contrary, the 80 km fixed compensator allows only small range of transmission around 80 km.

Fig. 24 (a) A perfect square eye diagram, (b) a closed eye diagram due to bandwidth, fiber impairments, noise, and timing jitter.

One brute-force method to achieve tunable dispersion compensation is to build a module with optical switches used to add or remove sections of fixed DCF to achieve a discrete set of dispersion compensation. Many other elegant, yet viable, approaches have been developed for tunable dispersion compensation, and these approaches include linearly chirped FBG with nonuniform heating, nonlinearly chirped Fiber Bragg grating (FBG) with a simple mechanical stretcher, virtually imaged phase array, electronic tap delay filter with weights, multiple stage all pass filter, etc.

System Performance Parameters

An eye diagram provides a simple and useful tool to visualize intersymbol interference between data bits. **Fig. 24(a)** shows a perfect eye diagram. A square bit stream (i.e., series of symbol '1's and '0's) is sliced into sub-bit stream with predetermined eye intervals (i.e., several bit periods), and displayed through bit analyzing equipment (e.g., digital channel analyzer), overlapping the sliced sub-bit stream in order to obtain the eye diagram. When a perfect transmitter and receiver (i.e., infinite receiver bandwidth with zero noise characteristics and jitter), and a perfect transmission media (i.e., no dispersion and nonlinearities) are used, the received eye diagram is shaped as a perfect rectangular. In reality, the transmitter and receiver have a limited bandwidth with noise and jitter, and the transmission media (i.e., optical fiber) has dispersion and nonlinearities. Therefore, the eye diagram deviates from the perfect rectangular shape. **Fig. 24(b)** shows the eye diagram close to a real situation. The shape of the eye is generally broadened and distorted (i.e., eye is closed) due to limited bandwidth and fiber impairments, and noise and timing jitter are added onto this broadened and distorted eye shape.

The Q-factor (q) is also an important system parameter widely used in long-distance optical transmission system design. It is defined as the electrical signal-to-noise ratio before the decision circuit at receiver. The Q-factor is directly related to bit-error-rate (BER: the percentage of bits that has an error relative to total number of bits received in a specific time) by: $BER = 0.5 \cdot \text{erfc}(q/2^{0.5})$, where $\text{erfc}(x)$ is the complementary error function. The Q-factor is a unitless linear ratio, and is expressed in dB by $20 \cdot \log(q)$. As a conventional relationship, Q-factor of 15.6 dB (i.e., linear ratio 6) is required to achieve $BER = 10^{-9}$. **Fig. 25** shows the relationship of eye diagram, Q-factor, and BER.

Power penalty (PP) is one of the most important system parameters, and is defined as the received optical power difference in dB with and without signal impairments at a specified BER (conventionally 10^{-9}), from measured BER versus optical power curve. Therefore, 1 dB PP means that a system with signal impairments requires 1 dB more optical power at the receiver in order to achieve the same BER performance compared to the system without signal impairments. **Fig. 26** shows the typical BER curve as a function of received optical power and PP. Note that PP reduces from ~ 3.5 dB to ~ 1 dB with dispersion compensation.

In long-haul and undersea transmission system with many EDFA chains, OSNR is an important system parameter to design and characterize the optical transport system. OSNR is defined as the ratio of the power of signal channel to the power of ASE in a specified optical bandwidth (conventionally 0.1 nm). The OSNR (in dB) of a signal channel at the end of the system is approximated by: $OSNR \text{ (dB)} = 58 + P_{\text{out}} - L_{\text{span}} - NF - 10 \log(N_{\text{amp}})$, when the system has N_{amp} fiber spans, span loss L_{span}

Fig. 25 The relationship of eye diagram, Q-factor, and BER (μ_1, μ_2 : mean levels of logic '1' and '0', σ_1, σ_2 : standard deviation of logic '1' and '0').

Fig. 26 BER curve and power penalty.

(in dB) followed by an optical amplifier with output power P_{out} (in dBm) per channel launched into the span and noise figure (NF) (in dB). As an example, a typical OSNR requirement for $\text{BER}=10^{-9}$ is about 17 dB at 10 Gb/s data rate. The required OSNR should be increased by 6 dB when the data rate is increased by a factor of 4. Improving the amplifier's NF can increase OSNR, and the improved OSNR can be used to increase the system reach, reducing the channel power in order to suppress the nonlinearities, etc.

Introduction

This article describes the development of optical fiber communication systems. After describing some of the motivations for using optical fiber communications and the advantages of this technology, the key milestones and the principal people involved in developing optical fibers and compatible light sources are presented. Following this, the article looks at the evolution of fielded systems and the use of optical fiber links in undersea applications.

One of the principal needs of people since antiquity has been to communicate. This need created interests in devising communication systems for sending messages from one distant place to another. Many forms of such systems have appeared over the years. The basic motivations behind each new one were either to improve the transmission fidelity, to increase the data rate so that more information could be sent, or to increase the transmission distance between relay stations. Prior to the nineteenth century, all communication systems operated at a very low information rate and involved only optical or acoustical means, such as signal lamps or horns. One of the earliest known optical transmission links, for example, was the use of a fire signal by the Greeks in the eighth century BC for sending alarms, calls for help, or announcements of special events.

The invention of the telegraph by Samuel FB Morse in 1838 ushered in the era of electrical communications. In the ensuing years an increasingly larger portion of the electromagnetic spectrum, shown in Fig. 1, was utilized for the conveying of information from one place to another. The reason for this trend is that, in electrical systems, the data usually are transferred over the communication channel by superimposing the information onto a sinusoidally varying electromagnetic wave, which is known as the carrier. When reaching its destination the information is removed from the carrier wave and processed as desired. Since the amount of information that can be transmitted is related directly to the frequency range over which the carrier operates, increasing the carrier frequency theoretically increases the available transmission bandwidth and, consequently, provides a larger information capacity. Thus the trend in electrical communication system developments was to employ progressively higher frequencies (shorter wavelengths), which offer corresponding increases in bandwidth or information capacity. This activity led to the birth of communication mechanisms such as radio, television, microwave, and satellite links.

Another important portion of the electromagnetic spectrum encompasses the optical region shown in Fig. 1. In contrast to electrical communications, transmission of information in an optical format is carried out, not by frequency modulation of the carrier but by varying the intensity of the optical power. Similar to the radio-frequency spectrum, two classes of transmission medium can be used: an atmospheric channel or a guided-wave channel. Whereas transmission of optical signals through the atmosphere was done thousands of years ago, the use of a guided-wave optical channel such as an optical fiber is a fairly recent application.

Fiber optic communication systems have a number of inherent advantages over their copper-based and radio-transmission counterparts. Fiber optic cable can transmit at a higher capacity, thereby reducing the number of physical lines and the amount of equipment needed for a given transmission span. The lower weight and smaller size of optical fibers offer a distinct advantage over heavy, bulky copper cables in crowded underground cable ducts, in ceiling-mounted cable trays, and in mobile platforms such as aircraft and ships. Their dielectric composition is an especially important feature of optical fibers, since this ensures freedom from electromagnetic interference between adjacent fibers, eliminates ground loops, and results in extremely low fiber-to-fiber crosstalk.

Fig. 1 Electromagnetic spectrum for electrical and optical communications.

In addition, an optical fiber affords a high degree of data security since the optical signal is well confined within the optical waveguide.

Optical Fiber Development

Since an atmospheric channel requires a line-of-sight link and because it can be adversely affected by weather conditions, a guided-wave channel is the preferred approach in most cases for communication system applications. A challenge in using an optical fiber channel is to have a flexible, low-loss medium that transfers the optical signal over long distances without significant attenuation and distortion. Glass is an obvious material for such applications. The earliest known glass was made around 2500 BC and glass already was drawn into fibers during the time of the Roman Empire. However, such glasses have very high attenuations and thus are not suitable for communication applications. One of the first known attempts of using optical fibers for communication purposes was a demonstration in 1930 by Heinrich Lamm of image transmission through a short bundle of optical fibers for potential medical imaging. However, no further work was done beyond the demonstration phase since the technology for producing reasonably low-loss fibers with good light confinement was not yet mature.

Further work and experiments continued on using optical fibers for image transmission and by 1960 glass-clad fibers had attenuations of about one decibel per meter. This attenuation allowed fibers to be used for medical imaging, but it was still much too high for communications. Optical fibers had attracted the attention of researchers at that time, because they were analogous in theory to plastic dielectric waveguides used in certain microwave applications. In 1961, Elias Snitzer demonstrated this similarity by drawing fibers with cores so small they carried light in only one waveguide mode. He published a classic theoretical description of single-mode fibers in May 1961. However, to be useful for communication systems, optical fibers would need to have a loss of no more than 10 or 20 decibels per kilometer.

As a reminder, decibels measure the ratio of the output power to the input power on a logarithmic scale. The abbreviation for a decibel is 'dB.' The power ratio in decibels is given by the expression ' $10 \log (\text{power out}/\text{power in})$.' As an example, a power loss of 20 dB over a 1-km distance in an optical fiber means that only 1% of the light injected into the fiber comes out of the other end. **Table 1** gives some typical examples of various power ratios and their decibel equivalents.

In the early 1960s Charles Kao pursued the idea of using a clad glass fiber for an optical waveguide, building on optical waveguide research being done at the Standard Telecommunication Laboratories in England. After he and George Hockman painstakingly examined the transparency properties of various types of glass, Kao made a prediction, in 1966, that losses of no more than 20 dB/km were possible in optical fibers. In July 1966, Kao and Hockman presented a detailed analysis for achieving such a loss level. Kao then went on to actively advocate and promote the prospects of fiber communications, which generated interest in laboratories around the world to reduce fiber loss. It took four years to reach Kao's predicted goal of 20 dB/km, and the final solution was different from what many had expected.

To understand the process of making a fiber, consider the schematic of a typical fiber structure shown in **Fig. 2**. A fiber consists of a solid dielectric (glass or plastic) cylinder of refractive index n_1 called the core. This is surrounded by a dielectric cladding which has a refractive index n_2 , that is less than n_1 , in order to achieve light guiding in the fiber. This structure is then encapsulated by a buffer coating to protect the fiber from abrasion and outside contaminants. The first step in making a fiber is to form the clear glass

Fig. 3 Attenuation versus wavelength approximation for silica fibers.

rod or tube called a preform. This normally is done by a vapor-phase oxidation process. The preform has two distinct regions that correspond to the core and cladding of the eventual fiber. Fibers are made from the preform by precision feeding it into a circular furnace that softens the end of the preform to the point where it can be drawn into a very thin filament which becomes the optical fiber.

Most researchers had tried to purify the compound glasses used for standard optics, which are easy to melt and draw into fibers. A different approach was taken at the Corning Glass Works where Robert Maurer, Donald Keck, and Peter Schultz started with fused silica. This material can be made extremely pure, but has a high melting point and a low refractive index. Silica has the approximate attenuation versus wavelength characteristic shown in Fig. 3. Note that for early silica fibers there are regions of low attenuation around 850, 1310, and 1550 nm, which the literature refers to as the first, second, and third windows, respectively. The large attenuation spikes in the 1000- and 1400-nm spectral regions are due to absorption by residual water molecules in the glass. Although ultra-pure material processing techniques can eliminate these spikes to produce what are known as full-spectrum or low-water-peak fibers, most installed fibers still have a relatively large attenuation between 1350 and 1500 nm.

Note that since the attenuation spikes no longer are present in various types of fibers, the idea of operating windows has been replaced by the concept of spectral bands. The International Telecommunications Union (ITU) has designated six spectral bands for use in intermediate-range and long-distance optical fiber communications within the 1260 to 1675-nm region. The regions, which are known by the letters O, E, S, C, L, and U, are defined as follows:

- Original Band (O-Band): 1260 to 1360 nm
- Extended Band (E-Band): 1360 to 1460 nm
- Short Band (S-Band): 1460 to 1530 nm
- Conventional Band (C-Band): 1530 to 1565 nm
- Long Band (L-Band): 1565 to 1625 nm
- Ultra-long Band (U-Band): 1625 to 1675 nm

The Corning team made cylindrical preforms by depositing purified materials from the vapor phase. To produce a fiber that has light guiding properties they carefully added controlled trace levels of titanium to the core to make its refractive index slightly higher than that of the cladding without raising the attenuation significantly. In September 1970, they announced the fabrication of single-mode fibers with an attenuation of 17 dB/km at the 633-nm helium-neon line. The fibers were fragile, but independent tests at the British Post Office Research Laboratories facility in Martlesham Heath, England confirmed the low loss.

This dramatic breakthrough was the first among the many developments that opened the door to fiber optic communications. The ensuing years saw further reductions in optical fiber attenuations. By mid-1972, Maurer, Keck, and Schultz at Corning had made multimode germania-doped fibers with a 4-dB/km loss and much greater strength than the earlier brittle titania-doped fibers. In order to couple a sufficient amount of optical power into a fiber, early applications used multimode fibers with a refractive-index gradient between core and cladding of around 2% and core diameters of 50 or 62.5 micrometers.

Single-mode fibers have much smaller core diameters on the order of 9 micrometers in order to allow only one propagation mode. This type of fiber has a much higher transmission capacity since the effect of modal dispersion is eliminated. The first single-mode fibers were optimized to have a zero dispersion value at 1310 nm, since the silica material used at that time exhibited a low

Fig. 4 Dispersion characteristics of three types of standard optical fibers.

loss within a spectral band around this wavelength. **Fig. 4** shows the dispersion characteristic of this type of fiber as a function of wavelength in the S-, C-, and L-bands. As a result of its widespread use in early single-mode transmission systems, this fiber design has been standardized by the International Telecommunication Union (ITU-T) under the designation Recommendation G.652.

Standard G.652 silica fibers provide the lowest attenuation at 1550 nm, but have a much larger signal dispersion at this wavelength than at 1310 nm. Since system designers wanted to use fibers at a 1550-nm wavelength, in order to transmit high-speed data over longer distances, fiber manufacturers overcame the larger signal dispersion limitation by creating the so-called dispersion-shifted fibers. This was done through a clever manipulation of the core and cladding designs that allowed the zero-dispersion point to shift to longer wavelengths. In particular, the ITU-T created a specification for operation at 1550 nm which is designated as recommendation G.653. **Fig. 4** also shows the dispersion characteristic of this type of fiber as a function of wavelength.

Although the G.652 and G.653 fibers work well for single-wavelength operation, a different type of fiber, having non-zero dispersion within a broad spectral range, is needed when implementing systems that use many independent light sources simultaneously within a particular wavelength band. This led to the specification of the non-zero dispersion shifted fiber (NZDSF) in the ITU-T Recommendation G.655 that are designated to operate around 1550 nm. The main purpose of having a positive dispersion value over the entire operating spectrum is to mitigate a nonlinear optical effect called four-wave mixing (FWM), which is analogous to intermodulation distortion in electrical systems. **Fig. 4** shows the dispersion characteristic of the G.655 fiber in the S-, C-, and L-bands.

Light Sources

The fiber by itself is not practical unless there is a compatible optical source for launching light signals into it. The most suitable device for this is a semiconductor light-emitting diode (LED) or a laser diode. In the 1960s, a great deal of effort took place to achieve laser action in pn-junction diodes. The early devices were GaAs and GaAsP lasers that operated at a temperature of 77 K, emitted at a wavelength around 850 nm, and had high lasing threshold current densities. To make devices that were more application-friendly by operating at room temperature, structures consisting of sandwiched layers of AlGaAs and GaAs were investigated. Finally, in 1970, researchers at Bell Laboratories and a team at the Ioffe Physical Institute in Leningrad made the first semiconductor diode lasers based on a layered AlGaAs/GaAs/AlGaAs structure that were able to emit continuous-wave light in the 850-nm region at room temperature.

Major improvements in laser diode performance and reliability followed this achievement during the next decade. In addition, around 1976, room-temperature laser diodes operating at longer wavelengths, in the 1100 to 1600-nm region, started to appear. Of particular interest were GaInAsP/InP-based laser diodes emitting in the 1310-nm and 1550-nm low-loss windows of optical fibers. The progressive development of ever-improving devices during the 1980s and 1990s, included single-frequency emission with narrow linewidths under continuous operation, low levels of chirp under direct modulation, high output power, and the ability to tune specially constructed laser diodes over a wavelength range of up to 30 nm.

Fielded Systems

The bit rate-distance product $B \times L$ where B is the transmission bit rate and L is the repeater spacing, measures the transmission capacity of optical fiber links. Since the inception of optical fiber communications in the mid-1970s, the link transmission capacity has experienced a tenfold increase every four years. Several major technology advances spurred this growth. Among the technology developments are laser diodes emitting over an extremely narrow spectral band, optical amplifiers, fibers with low losses and low dispersions, and the concepts of wavelength division multiplexing.

Some of the initial telephone-system field trials in the USA were carried out in 1977 by GTE in Los Angeles and by AT&T in Chicago. These transmission links were largely for the trunking of telephone lines, which are digital links consisting of

Table 2 Commonly used SONET and SDH transmission rates

<i>SONET level</i>	<i>Electrical level</i>	<i>Line rate (Mb/s)</i>	<i>SDH equivalent</i>	<i>Common rate name</i>
OC-1	STS-1	51.84	–	
OC-3	STS-3	155.52	STM-1	155 Mb/s
OC-12	STS-12	622.08	STM-4	622 Mb/s
OC-24	STS-24	1244.16	STM-8	
OC-48	STS-48	2488.32	STM-16	2.5 Gb/s
OC-96	STS-96	4976.64	STM-32	
OC-192	STS-192	9953.28	STM-64	10 Gb/s
OC-768	STS-768	9,813.12	STM-256	40 Gb/s

time-division-multiplexed 64-kb/s voice channels. Similar demonstrations were carried out in Europe and Japan. Applications ranged from 45 to 140 Mb/s with repeater spacings around 10 km.

With the advent of high-capacity fiber optic transmission lines in the 1980s, service providers established a standard signal format called synchronous optical network (SONET) in North America and synchronous digital hierarchy (SDH) in other parts of the world. These standards define a synchronous frame structure for sending multiplexed digital traffic over optical fiber trunk lines. The basic building block and first level of the SONET signal hierarchy is called the synchronous transport signal–level 1 (STS-1), which has a bit rate of 51.84 Mb/s. Higher-rate SONET signals are obtained by byte-interleaving N STS-1 frames, which are then scrambled and converted to an optical carrier–level N (OC- N) signal. Thus the OC- N signal will have a line rate exactly N times that of an OC-1 signal. For SDH systems, the fundamental building block is the 155.52-Mb/s synchronous transport module–level 1 (STM-1). Again, higher-rate information streams are generated by synchronously multiplexing N different STM-1 signals to form the STM- N signal. Table 2 shows commonly used SDH and SONET signal levels.

The development of optical sources and photodetectors capable of operating at 1310 nm allowed a shift in the transmission wavelength from 850 nm to 1310 nm. This resulted in a substantial increase in the repeaterless transmission distance for long-haul telephone trunks, since optical fibers exhibit lower power loss and less signal dispersion at 1310 nm. Intercity applications first used multimode fibers, but in 1984 switched exclusively to single-mode fibers, which have a significantly larger bandwidth. Bit rates for long-haul links typically range between 155 and 622 Mb/s (OC-3 and OC-12), and in some cases up to 2.5 Gb/s (OC-48), over repeater spacings of 40 km. Both multimode and single-mode 1310-nm fibers are used in local area networks, where bit rates range from 10 Mb/s to 100 Mb/s over distances ranging from 500 m to tens of kilometers.

In the next step of system evolution, links operating in the low-loss window around 1550 nm attracted much attention for high-capacity, long-span terrestrial and undersea transmission links. These links routinely carry traffic at 2.5 Gb/s over 90-km repeaterless distances. By 1996, advances in high-quality lasers and receivers allowed single-wavelength transmission rates of 10 Gb/s (OC-192).

In 1989, the introduction of optical amplifiers gave a major boost to fiber transmission capacity. Although there are GaAlAs-based solid-state optical amplifiers for the first window and InGaAsP amplifiers for the second window, the most successful and widely used devices are erbium-doped fiber amplifiers (commonly called EDFAs) operating in the 1530 to 1560-nm range and Raman fiber amplifiers that are used for operation in the 1560 to 1600-nm region.

During the same time period, impressive demonstrations of long-distance high-capacity systems were made using optical soliton signals. A soliton is a nondispersive pulse that makes use of nonlinear dispersion properties in a fiber to cancel out chromatic dispersion effects. As an example, solitons at rates of 10 Gb/s have been sent over a 12200-km experimental link using optical amplifiers and special modulation techniques.

Entrance of Wavelength Division Multiplexing

The use of wavelength division multiplexing (WDM) offers a further boost in fiber transmission capacity. The basis of WDM is to use multiple sources operating at slightly different wavelengths to transmit several independent information streams over the same fiber. Although researchers started looking at WDM in the 1970s, during the ensuing years it generally turned out to be easier to implement higher-speed electronic and optical devices than to invoke the greater system complexity called for in WDM. However, a dramatic surge in WDM popularity started in the early 1990s, as electronic devices neared their modulation limit and high-speed equipment became increasingly complex.

Fig. 5 shows the concept of implementing many closely spaced wavelengths within a spectral band centered around 1552.524 nm. This scheme is referred to as dense WDM or DWDM. Conceptually, the DWDM scheme is the same as frequency division multiplexing (FDM) used in microwave radio and satellite systems. Just as in FDM, the wavelengths (or optical frequencies) in a DWDM link must be properly spaced to avoid interference between channels. In an optical system this interference may arise from the fact that the center wavelength of laser diode sources and the spectral operating characteristics of other optical components in the link may drift with temperature and time, thereby giving rise to the need for a guard band between wavelength channels.

Since WDM is essentially frequency division multiplexing at optical carrier frequencies, the ITU developed DWDM standards that specify channel spacings in terms of frequency. The ITU-T Recommendation G.694.1, which is entitled ‘Dense Wavelength

Fig. 5 Wavelength division multiplexing (WDM) concept.

Division Multiplexing (DWDM), specifies WDM operation in the S-, C-, and L-bands for high-quality, high-rate metro area network (MAN) and wide area network (WAN) services. It calls out for narrow frequency spacings of 100 to 12.5 GHz (or, equivalently, 0.8 to 0.1 nm at 1550 nm). This implementation requires the use of stable, high-quality, temperature-controlled and wavelength-controlled (frequency-locked) laser diode light sources.

With the production of full-spectrum (low-water-content) fibers, the development of relatively inexpensive optical sources, and the desire to have low-cost optical links operating in metro and local area networks, came the concept of coarse WDM (CWDM). In 2002, the ITU-T released a standard aimed specifically at CWDM. This is Recommendation G.694.2, which is entitled 'Coarse Wavelength Division Multiplexing (CWDM)'. The CWDM grid is made up of 18 wavelengths defined within the range 1270 nm to 1610 nm (O-through L-bands) spaced by 20 nm with wavelength-drift tolerances of ± 2 nm. This can be achieved with inexpensive light sources that are not temperature-controlled. The targeted transmission distance for CWDM is 50 km on single-mode fibers, such as those specified in ITU-T Recommendations G.652, G.653, and G.655.

Wavelength tunability of a source is an important property of WDM systems. Obviously it is not desirable or practical to maintain an inventory of dozens of lasers that emit at different wavelengths for WDM applications. The ideal tunable laser should be adjustable to emit at a specific wavelength across a broad spectral range. One such device is a distributed Bragg reflector (DBR) laser diode that can be tuned over a 10 to 20 nm spectral range. Work on perfecting such devices are still underway.

Starting in the mid-1990s, a combination of EDFAs and WDM was used to boost fiber information capacity to even higher levels and to increase the transmission distance. A major system consideration in these super-high capacity links is to ensure that there is appropriate link and equipment redundancy, so that alternate paths are available in case of disruptions in communications resulting from cable ruptures (for example, caused by errant digging from a backhoe) or equipment failures at an intermediate node. Such disruptions otherwise could have a devastating effect on a large group of users.

Undersea Optical Cable Systems

The first transoceanic fiber optic cable systems were installed in the Atlantic and Pacific Oceans in 1988 and 1989. Initially these systems operated at 280 Mb/s per fiber pair using 1310-nm lasers and single-mode fibers. The links consisted of a series of point-to-point optical fiber segments between electronic-based undersea regeneration points that were located nominally 60 km apart. Later the transmission capacity of these links was upgraded to 2.5 Gb/s and the regenerator spacing was increased to 100 km by converting the 1310-nm multiple-frequency light sources to 1550-nm single-frequency laser diodes. Later, the regenerator spacing was increased to 140 km.

Although these cable systems significantly improved the quality of the international telephone service, the optical-to-electrical conversion process at each regeneration point remained a capacity bottleneck. The introduction of erbium-doped optical fiber amplifiers (EDFA) eliminated this bottleneck from undersea lightwave systems by amplifying signals directly in the optical domain. Since EDFAs operate over a 30-nm wavelength band, they are well suited for use with undersea WDM links, which have provided a further capacity increase. These undersea optical amplifiers are typically spaced about 45 km apart.

One example of the many worldwide installations of optically amplified WDM networks is the SEA-ME-WE-3 Cable System. This undersea network runs from Germany to Singapore, connecting more than a dozen countries in between. Hence the name SEA-ME-WE, which refers to Southeast Asia (SEA), the Middle East (ME), and Western Europe (WE). The network has two pairs of undersea fibers with a capacity of eight STM-16 wavelengths per fiber.

Glossary

Chromatic dispersion The time-domain pulse broadening in an optical fiber caused by the frequency dependence of the refractive index. This results in photons at different frequencies traveling at different speeds [ps/nm/km].

Chromatic dispersion slope Different wavelengths have different amounts of dispersion values in an optical fiber [ps/nm²/km].

Conventional single mode fiber (SMF) Fiber that transmits only a single optical mode by virtue of a very small core diameter relative to the cladding. Provides lowest loss in the 1,550 nm region and has zero dispersion at 1,300 nm.

Cross-phase modulation (XPM) A nonlinear Kerr effect in which a signal undergoes a nonlinear phase shift induced by a copropagating signal at a different wavelength in a WDM system.

Dispersion compensating fiber (DCF) Optical fiber that has both a large negative dispersion and dispersion slope around 1,550 nm.

Fiber Bragg gratings (FBGs) A small section of optical fiber in which there is a periodic change of refractive index along the core of the fiber. An FBG acts as a wavelength-selective mirror, reflecting only specific wavelengths (Bragg wavelengths) and passing others.

Four-wave mixing (FWM) A nonlinear Kerr effect in which two or more signal wavelengths interact to generate a new wavelength.

Kerr effect Nonlinear effect in which the refractive index of optical fiber varies as a function of the intensity of light within the fiber core.

Modulation The process of encoding digital data onto an optical signal so it can be transmitted through an optical network.

Nonlinear effects Describes the nonlinear responses of a dielectric to intense electromagnetic fields. One such effect is the intensity dependence of the refractive index of an optical fiber (Kerr effect).

Nonzero dispersion-shifted fiber (NZDSF) Optical fiber that has a small amount of dispersion in the 1,550 nm region in order to reduce deleterious nonlinear effects.

Polarization mode dispersion (PMD) Dispersion resulting from the fact that different light polarizations within the fiber core will travel at different speeds through the optical fiber [ps/km^{0.5}].

Self-phase modulation (SPM) A nonlinear Kerr effect in which a signal undergoes a self-induced phase shift during propagation in optical fiber.

Wavelength division multiplexing (WDM) Transmitting many different wavelengths down the same optical fiber at the same time in order to increase the amount of information that can be carried.

Introduction

Optical communications systems have grown explosively in terms of the capacity that can be transmitted over a single optical fiber. This trend has been fueled by two complementary techniques, those being the increase in data-rate-per-channel coupled with the increase in the total number of parallel wavelength channels. However, there are many considerations as to the total number of wavelength-division-multiplexed (WDM) channels that can be accommodated in a system, including cost, information spectral efficiency, nonlinear effects, and component wavelength selectivity.

Dispersion is one of the critical roadblocks to increasing the transmission capacity of optical fiber. The dispersive effect in an optical fiber has several ingredients, including intermodal dispersion in a multimode fiber, waveguide dispersion, material dispersion, and chromatic dispersion. In particular, chromatic dispersion is one of the critical effects in a single mode fiber (SMF), resulting in a temporal spreading of an optical bit as it propagates along the fiber. At data rates ≤ 2.5 Gbit/s, the effects of chromatic dispersion are not particularly troublesome. For data rates ≥ 10 Gbit/s, however, transmission can be tricky and the chromatic dispersion-induced degrading effects must be dealt with in some way, perhaps by compensation. Furthermore, the effects of chromatic dispersion rise quite rapidly as the bit rate increases – when the bit rate increases by a factor of four, the effects of chromatic dispersion increase by a factor of 16! This article will only deal with the management of chromatic dispersion in single mode fiber.

One of the critical limitations of optical fiber communications comes from chromatic dispersion, which results in a pulse broadening as it propagates along the fiber. This occurs as photons of different frequencies (created by the spreading effect of data modulation) travel at different speeds, due to the frequency-dependent refractive index of the fiber core. Compounding the problems caused by chromatic dispersion is the fact that as bit rates rise, chromatic dispersion effects rise quadratically with respect to the increase in the bit rate. One can eliminate these effects using fiber with zero chromatic dispersion, known as dispersion shifted fiber (DSF). However, with zero dispersion, all channels in a wavelength-division-multiplexed (WDM) system travel at the

same speed, in-phase, and a number of deleterious nonlinear effects such as cross-phase modulation (XPM) and four-wave mixing (FWM) result. Thus, in WDM systems, some amount of chromatic dispersion is necessary to keep channels out-of-phase, and as such chromatic dispersion compensation is required. Any real fiber link may also suffer from 'dispersion slope' effects, in which a slightly different dispersion value is produced in each WDM channel. This means that while one may be able to compensate one channel exactly, other channels may progressively accumulate increasing amounts of dispersion, which can severely limit the ultimate length of the optical link and the wavelength range that can be used in a WDM system. This article will address the concepts of chromatic dispersion and dispersion slope management followed by some examples highlighting the need for tunability to enable robust optical WDM systems in dynamic environments. Some dispersion monitoring techniques are then discussed and examples given.

Chromatic Dispersion in Optical Fiber Communication Systems

In any medium (other than vacuum) and in any waveguide structure (other than ideal infinite free space), different electromagnetic frequencies travel at different speeds. This is the essence of chromatic dispersion. As the real fiber-optic world is rather distant from the ideal concepts of both vacuum and infinite free space, dispersion will always be a concern when one is dealing with the propagation of electromagnetic radiation through fiber. The velocity in fiber of a single monochromatic wavelength is constant. However, data modulation causes a broadening of the spectrum of even the most monochromatic laser pulse. Thus, all modulated data have a nonzero spectral width which spans several wavelengths, and the different spectral components of modulated data travel at different speeds. In particular, for digital data intensity modulated on an optical carrier, chromatic dispersion leads to pulse broadening – which in turn leads to chromatic dispersion limiting the maximum data rate that can be transmitted through optical fiber (see Fig. 1).

Considering that the chromatic dispersion in optical fibers is due to the frequency-dependent nature of the propagation characteristics, for both the material (the refractive index of glass) and the waveguide structure, the speed of light of a particular wavelength λ will be expressed as follows, using a Taylor series expansion of the value of the refractive index as a function of the wavelength:

$$v(\lambda) = \frac{c_0}{n(\lambda)} = \frac{c_0}{n_0(\lambda_0) + \frac{\partial n}{\partial \lambda} \delta \lambda + \frac{\partial^2 n}{\partial \lambda^2} (\delta \lambda)^2} \quad (1)$$

Here, c_0 is the speed of light in vacuum, λ_0 is a reference wavelength, and the terms in $\partial n / \partial \lambda$ and $\partial^2 n / \partial \lambda^2$ are associated with the chromatic dispersion and the dispersion slope (i.e., the variation of the chromatic dispersion with wavelength), respectively. Transmission fiber has positive dispersion, i.e. longer wavelengths result in longer propagation delays. The units of chromatic dispersion are picoseconds per nanometer per kilometer, meaning that shorter time pulses, wider frequency spread due to data modulation, and longer fiber lengths will each contribute linearly to temporal dispersion. Higher data rates inherently have both shorter pulses and wider frequency spreads. Therefore, as network speed increases, the impact of chromatic dispersion rises precipitously as the square of the increase in data rate. The quadratic increase with the data rate is a result of two effects, each with a linear contribution. On one hand, a doubling of the data rate makes the spectrum twice as wide, doubling the effect of dispersion. On the other hand, the same doubling of the data rate makes the data pulses only half as long (hence twice as sensitive to dispersion). The combination of a wider signal spectrum and a shorter pulse width is what leads to the overall quadratic impact. Moreover, the data modulation format used can significantly affect the sensitivity of a system to chromatic dispersion. For example, the common nonreturn-to-zero (NRZ) data

Fig. 1 The origin of chromatic dispersion in data transmission. (a) Chromatic dispersion is caused by the frequency-dependent refractive index in fiber. (b) The nonzero spectral width due to data modulation. (c) Dispersion leads to pulse broadening, proportional to the transmission distance and the data rate.

format, in which the optical power stays high throughout the entire time slot of a '1' bit, is more robust to chromatic dispersion than is the return-to-zero (RZ) format, in which the optical power stays high in only part of the time slot of a '1' bit. This difference is due to the fact that RZ data have a much wider channel frequency spectrum compared to NRZ data, thus incurring more chromatic dispersion. However, in a real WDM system, the RZ format increases the maximum allowable transmission distance by virtue of its reduced duty cycle (compared to the NRZ format), making it less susceptible to fiber nonlinearities as can be seen in Fig. 2.

A rule for the maximum distance over which data can be transmitted is to consider a broadening of the pulse equal to the bit period. For a bit period B , a dispersion value D and a spectral width $\Delta\lambda$, the dispersion-limited distance is given by

$$L_D = \frac{1}{D \cdot B \cdot \Delta\lambda} = \frac{1}{D \cdot B \cdot (cB)} \propto \frac{1}{B^2} \quad (2)$$

(see Fig. 3). For example, for single mode fiber, $D=17$ ps/nm/km, so for 10 Gbit/s data the distance is $L_D=52$ km. In fact, a more exact calculation shows that for 60 km, the dispersion induced power penalty is less than 1 dB (see Fig. 4). The power penalty for uncompensated dispersion rises exponentially with transmission distance, and thus to maintain good signal quality, dispersion compensation is required.

Chromatic Dispersion Management

Optical Nonlinearities as Factors to be Considered in Dispersion Compensation

Even though it is possible to manufacture fiber with zero dispersion, it is not practical to use such fiber for WDM transmission, due to large penalties induced by fiber nonlinearities. Most nonlinear effects originate from the nonlinear refractive index of fiber, which is not only dependent on the frequency of light but also on the intensity (optical power), and is related to the optical

Fig. 4 Power penalties due to uncompensated dispersion in single mode fiber (SMF) as a function of distance and data rate. Reproduced with permission from Garrett LD (2001) Invited Short Course, *Optical Fiber Communication Conference*.

power as:

$$\bar{n}(f, P) = n(f) + n_2 \frac{P}{A_{\text{eff}}} \quad (3)$$

where $n(f)$ is the linear part of the refractive index, P is the optical power inside the fiber, and n_2 is the nonlinear-index coefficient for silica fibers. The typical value of n_2 is $2.6 \times 10^{-20} \text{ m}^2/\text{W}$. This number takes into account the averaging of the polarization states of the light as it travels in the fiber. The intensity dependence of the refractive index gives rise to three major nonlinear effects.

Self-phase modulation (SPM)

A million photons 'see' a different glass than does a single photon, and a photon traveling along with many other photons will slow down. SPM occurs because of the varying intensity profile of an optical pulse on a single WDM channel. This intensity profile causes a refractive index profile and, thus, a photon speed differential. The resulting phase change for light propagating in an optical fiber is expressed as:

$$\Phi_{\text{NL}} = \gamma P L_{\text{eff}} \quad (4)$$

where the quantities γ and L_{eff} are defined as:

$$\gamma = \frac{2\pi n_2}{\lambda A_{\text{eff}}} \quad \text{and} \quad L_{\text{eff}} = \frac{1 - e^{-\alpha L}}{\alpha} \quad (5)$$

where A_{eff} is the effective mode area of the fiber and α is the fiber attenuation loss. L_{eff} is the effective nonlinear length of the fiber that accounts for fiber loss, and γ is the nonlinear coefficient measured in $\text{rad}/\text{km}/\text{W}$. A typical range of values for γ is between 10–30 $\text{rad}/\text{km}/\text{W}$. Although the nonlinear coefficient is small, the long transmission lengths and high optical powers, that have been made possible by the use of optical amplifiers, can cause a large enough nonlinear phase change to play a significant role in state-of-the-art lightwave systems.

Cross-phase modulation (XPM)

When considering many WDM channels co-propagating in a fiber, photons from channels 2 through N can distort the index profile that is experienced by channel 1. The photons from the other channels 'chirp' the signal frequencies on channel 1, which will interact with fiber chromatic dispersion and cause temporal distortion. This effect is called cross-phase modulation. In a two-channel system, the frequency chirp in channel 1, due to power fluctuation within both channels, is given by

$$\Delta B = \frac{d\Phi_{\text{NL}}}{dt} = \gamma L_{\text{eff}} \frac{dP_1}{dt} + 2\gamma L_{\text{eff}} \frac{dP_2}{dt} \quad (6)$$

where, dP_1/dt and dP_2/dt are the time derivatives of the pulse powers of channels 1 and 2, respectively. The first term on the right-hand side of the above equation is due to SPM, and the second term is due to XPM. Note that the XPM-induced chirp term is double that of the SPM-induced chirp term. As such, XPM can impose a much greater limitation on WDM systems than can SPM, especially in systems with many WDM channels.

Four-wave-mixing (FWM)

The optical intensity propagating through the fiber is related to the electric field intensity squared. In a WDM system, the total electric field is the sum of the electric fields of each individual channel. When squaring the sum of different fields, products emerge that are beat terms at various sum and difference frequencies to the original signals. Fig. 5 depicts that if a WDM channel exists at

Fig. 5 (a) and (b) FWM induces new spectral components via nonlinear mixing of two wavelength signals. (c) The signal degradation due to FWM products falling on a third data channel can be reduced by even small amounts of dispersion. LEAF	4.0	0.085	≤ 0.25	9.6	≤ 0.08
Standard DCF	− 90	− 0.22	≤ 0.5	5.2	≤ 0.08

one of the four-wave-mixing beat-term frequencies, then the beat term will interfere coherently with this other WDM channel and potentially destroy the data.

Dispersion Maps

While zero-dispersion fiber is not a good idea, a large value of the accumulated dispersion at the end of a fiber link is also undesirable. An ideal solution is to have a ‘dispersion map,’ alternating sections of positive and negative dispersion as can be seen in [Fig. 6](#). This is a very powerful concept: at each point along the fiber the dispersion has some nonzero value, eliminating FWM and XPM, but the total dispersion at the end of the fiber link is zero, so that no pulse broadening is induced ([Table 1](#)). The most advanced systems require periodic dispersion compensation, as well as pre- and post-compensation (before and after the transmission fiber).

The addition of negative dispersion to a standard fiber link has been traditionally known as ‘dispersion compensation,’ however, the term ‘dispersion management’ is more appropriate. SMF has positive dispersion, but some new varieties of nonzero

Fig. 7 Chromatic dispersion characteristics of various commercially available types of transmission fiber.

Fig. 8 Various dispersion maps for SMF-DCF and NZDSF-SMF.

dispersion-shifted fiber (NZDSF) come in both positive and negative dispersion varieties. Some examples are shown in [Fig. 7](#). Reverse dispersion fiber is also now available, with a large dispersion comparable to that of SMF, but with the opposite sign. When such flexibility is available in choosing both the magnitude and sign of the dispersion of the fiber in a link, dispersion-managed systems can be fully optimized to the desired dispersion map using a combination of fiber and dispersion compensation devices (see [Fig. 8](#)).

Dispersion is a linear process, so first-order dispersion maps can be understood as linear systems. However, the effects of nonlinearities cannot be ignored, especially in WDM systems, with many tens of channels, where the launch power may be very high. In particular, in systems deploying dispersion compensating fiber (DCF), the large nonlinear coefficient of the DCF can dramatically affect the dispersion map.

Corrections to Linear Dispersion Maps

Chromatic dispersion is a necessity in WDM systems, to minimize the effects of fiber nonlinearities. A chromatic dispersion value as small as a few ps/nm/km is usually sufficient to make XPM and FWM negligible. To mitigate the effects of nonlinearities but maintain small amounts of chromatic dispersion, NZDSF is commercially available. Due to these nonlinear effects, chromatic dispersion must be managed, rather than eliminated.

If a dispersion-management system was perfectly linear, it would be irrelevant whether the dispersion along a path is small or large, as long as the overall dispersion is compensated to zero (end to end). Thus, in a linear system the performance should be similar, regardless of whether the transmission fiber is SMF, and dispersion compensation modules are deployed every 60 km, or the transmission fiber is NZDSF (with approximately a quarter of the dispersion value of SMF) and dispersion compensation modules are deployed every 240 km. In real life, optical nonlinearities are very important, and recent results seem to favor the use of large, SMF-like, dispersion values in the transmission path and correspondingly high dispersion compensation devices. A recent

study of performance versus channel spacing showed that the capacity of SMF could be more than four times that of NZDSF. This is because the nonlinear coefficients are much higher in NZDSF than in SMF, and for dense WDM the channel interactions become a limiting factor. A critical conclusion is that not all dispersion compensation maps are created equal: a simple calculation of the dispersion compensation, to cancel the overall dispersion value, does not lead to optimal dispersion map designs.

Additionally, several solutions have been shown to be either resistant to dispersion, or have been shown to rely on dispersion itself for transmission. Such solutions include chirped pulses (where prechirping emphasizes the spectrum of the pulses so that dispersion does not broaden them too much), dispersion assisted transmission (where an initial phase modulation tailored to the transmission distance leads to full-scale amplitude modulation at the receiver end due to the dispersion), and various modulation formats robust to chromatic dispersion and nonlinearities.

Dispersion Management Solutions

Fixed Dispersion Compensation

From a systems point of view, there are several requirements for a dispersion compensating module: low loss, low optical nonlinearity, broadband (or multichannel) operation, small footprint, low weight, low power consumption, and clearly low cost. It is unfortunate that the first dispersion compensation modules, based on DCF only, met two of these requirements: broadband operation and low power consumption. On the other hand, several solutions have emerged that can complement or even replace these first-generation compensators.

Dispersion compensating fiber (DCF)

One of the first dispersion compensation techniques was to deploy specially designed sections of fiber with negative chromatic dispersion. The technology for DCF emerged in the 1980s and has developed dramatically since the advent of optical amplifiers in 1990. DCF is the most widely deployed dispersion compensator, providing broadband operation and stable dispersion characteristics, and the lack of a dynamic, tunable DCF solution has not reduced its popularity.

As can be seen in Fig. 9, the core of the average dispersion compensating fiber is much smaller than that of standard SMF, and beams with longer wavelengths experience relatively large changes in mode size (due to the waveguide structure) leading to greater propagation through the cladding of the fiber, where the speed of light is greater than that of the core. This leads to a large negative dispersion value. Additional cladding layers can lead to improved DCF designs that can include negative dispersion slope to counteract the positive dispersion slope of standard SMF.

In spite of its many advantages, DCF has a number of drawbacks. First, it is limited to a fixed compensation value. In addition, DCF has a weakly guiding structure and has a much smaller core cross-section, $19 \mu\text{m}^2$, compared to the $85 \mu\text{m}^2$ of SMF. This leads to higher nonlinearity, higher splice losses, as well as higher bending losses. Last, the length of DCF required to compensate for SMF dispersion is rather long, about one-fifth of the length of the transmission fiber for which it is compensating. Thus DCF modules induce loss, and are relatively bulky and heavy. The bulk is partly due to the mass of fiber, but also due to the resin used to hold the fiber securely in place. One other contribution to the size of the module is the higher bend loss associated with the refractive index profile of DCF; this limits the radius of the DCF loop to 6–8 inches, compared to the minimum bend radius of 2 inches for SMF.

Traditionally, DCF-based dispersion compensation modules are usually located at amplifier sites. This serves several purposes. First, amplifier sites offer relatively easy access to the fiber, without requiring any digging or unbraiding of the cable. Second, DCF

Fig. 9 Typical DCF (a) refractive index profile and (b) dispersion and loss as a function of wavelength. Δn is defined as refractive index variation relative to the cladding.

has high loss (usually at least double that of standard SMF), so a gain stage is required before the DCF module to avoid excessively low signal levels. DCF has a cross-section four times smaller than SMF, hence a higher nonlinearity, which limits the maximum launch power into a DCF module. The compromise is to place the DCF in the mid-section of a two-section EDFA. This way, the first stage provides pre-DCF gain, but not to a power level that would generate excessive nonlinear effects in the DCF. The second stage amplifies the dispersion compensated signal to a power level suitable for transmission through the fiber link. This launch power level is typically much higher than could be transmitted through DCF without generating large nonlinear effects. Many newer dispersion compensation devices have better performance than DCF, in particular lower loss and lower nonlinearities. For this reason, they may not have to be deployed at the mid-section of an amplifier. Fig. 10 shows the real demonstration results using the DCF.

Chirped fiber Bragg gratings

Fiber Bragg gratings have emerged as major components for dispersion compensation because of their low loss, small footprint, and low optical nonlinearity. Bragg gratings are sections of single-mode fiber in which the refractive index of the core is modulated in a periodic fashion, as a function of the spatial coordinate along the length of the fiber. When the spatial periodicity of the modulation matches what is known as a Bragg condition with respect to the wavelength of light propagating through the grating, the periodic structure acts like a mirror, reflecting the optical radiation that is traveling through the core of the fiber. An optical circulator is traditionally used to separate the reflected output beam from the input beam.

When the periodicity of the grating is varied along its length, the result is a chirped grating which can be used to compensate for chromatic dispersion. The chirp is understood as the rate of change of the spatial frequency as a function of position along the grating. In chirped gratings the Bragg matching condition for different wavelengths occurs at different positions along the grating length. Thus, the roundtrip delay of each wavelength can be tailored by designing the chirp profile appropriately. Fig. 11 compares the chirped FBG with uniform FBG. In a data pulse that has been distorted by dispersion, different frequency components arrive

Fig. 10 System demonstration of dispersion compensation using DCF. Reproduced with permission from Park YK, Yeates PD, Delavaux J-MP, *et al.* (1995) A field demonstration of 20-Gb/s capacity transmission over 360 km of installed standard (non-DSF) fiber. *Photon. Technol. Lett.* 7 (7): 816–818.

Fig. 11 Uniform and chirped FBGs. (a) A grating with uniform pitch has a narrow reflection spectrum and a flat time delay as a function of wavelength. (b) A chirped FBG has a wider bandwidth, a varying time delay and a longer grating length.

with different amounts of relative delay. By tailoring the chirp profile such that the frequency components see a relative delay which is the inverse of the delay of the transmission fiber, the pulse can be compressed back. The dispersion of the grating is the slope of the time delay as a function of wavelength, which is related to the chirp.

The main drawback of Bragg gratings is that the amplitude profile and the phase profile as a function of wavelength have some amount of ripple. Ideally, the amplitude profile of the grating should have a flat (or rounded) top in the passband, and the phase profile should be linear (for linearly chirped gratings) or polynomial (for nonlinearly chirped gratings). The grating ripple is the deviation from the ideal profile shape. Considerable effort has been expended on reducing the ripple. While early gratings were plagued by more than 100 ps of ripple, published results have shown vast improvement to values close to ± 3 ps.

Higher order mode dispersion compensation fiber

One of the challenges of designing standard DCF is that high negative dispersion is hard to achieve unless the cross-section of the fiber is small (which leads to high nonlinearity and high loss). One way to reduce both the loss and the nonlinearity is to use a higher-order mode (HOM) fiber (LP_{11} or LP_{02} near cutoff instead of the LP_{01} mode in the transmission fiber).

Such a device requires a good-quality mode converter between LP_{01} and LP_{02} to interface between the SMF and HOM fiber. HOM fiber has a dispersion per unit length greater than six times that of DCF. Thus, to compensate for a given transmission length in SMF, the length of HOM fiber required is only one sixth the length of DCF. Thus, even though losses and nonlinearity per unit length are larger for HOM fiber than for DCF, they are smaller overall, because of the shorter HOM fiber length. As an added bonus, the dispersion can be tuned slightly by changing the cutoff wavelength of LP_{02} (via temperature tuning). A soon to be released HOM fiber-based commercial dispersion compensation module is not tunable, but can fully compensate for dispersion slope.

Tunable Dispersion Compensation

The need for tunability

In a perfect world, all fiber links would have a known, discrete, and unchanging value of chromatic dispersion. Network operators would then deploy fixed dispersion compensators periodically along every fiber link to exactly match the fiber dispersion. Unfortunately, several vexing issues may necessitate that dispersion compensators are tunability, that they have the ability to adjust the amount of dispersion to match system requirements.

First, there is the most basic business issue of inventory management. Network operators typically do not know the exact length of a deployed fiber link nor its chromatic dispersion value. Moreover, fiber plants periodically undergo upgrades and maintenance, leaving new and nonexact lengths of fiber behind. Therefore, operators would need to keep in stock a large number of different compensator models, and even then the compensation would only be approximate. Second, we must consider the sheer difficulty of 40 Gbit/s signals. The tolerable threshold for accumulated dispersion for a 40 Gbit/s data channel is 16 times smaller than at 10 Gbit/s. If the compensation value does not exactly match the fiber to within a few percent of the required dispersion value, then the communication link will not work. Tunability is considered a key enabler for this bit rate (see Figs. 12 and 13). Third, the accumulated dispersion changes slightly with temperature, which begins to be an issue for 40 Gbit/s systems and 10 Gbit/s ultra long-haul systems. In fiber, the zero-dispersion wavelength changes with temperature at a typical rate of 0.03 nm/°C. It can be shown that a not-uncommon 50 °C variation along a 1,000 km 40 Gbit/s link can produce significant degradation (see Fig. 14). Fourth, we are experiencing the dawn of reconfigurable optical networking. In such systems, the network path, and therefore the accumulated fiber dispersion, can change. It is important to note that even if the fiber spans are compensated span-by-span, the pervasive use of compensation at the transmitter and receiver suggests that optimization and tunability based on path will still be needed.

Other issues that increase the need for tunability include: (i) laser and (de)mux wavelength drifts for which a data channel no longer resides on the flat-top portion of a filter, thereby producing a chirp on the signal that interacts with the fiber's chromatic dispersion; (ii) changes in signal power that change both the link's nonlinearity and the optimal system dispersion map; and (iii) small differences that exist in transmitter-induced signal chirp.

Fig. 12 The need for tunability. The tolerance of OC-768 systems to chromatic dispersion is 16 times lower than that of OC-192 systems. Approximate compensation by fixed in-line dispersion compensators for a single channel may lead to rapid accumulation of unacceptable levels of residual chromatic dispersion.

Fig. 13 Tunable dispersion compensation at OC-768 (40 Gb/s) is essential for achieving a comfortable range of acceptable transmission distances (80 km for tunable, only ~4 km for fixed compensation).

Fig. 14 Accumulated dispersion changes as a function of the link length and temperature fluctuation along the fiber link.

Approaches to tunable dispersion compensation

A host of techniques for tunable dispersion compensation have been proposed in recent years. Some of these ideas are just interesting research ideas, but several have strong potential to become viable technologies.

Fiber gratings offer the inherent advantages of fiber compatibility, low loss, and low cost. If a FBG has a refractive-index periodicity that varies nonlinearly along the length of the fiber, it will produce a time delay that also varies nonlinearly with wavelength (see Fig. 15). Herein lies the key to tunability. When a linearly chirped grating is stretched uniformly by a single mechanical element, the time delay curve is shifted towards longer wavelengths, but the slope of the ps-vs.-nm curve remains constant at all wavelengths within the passband. When a nonlinearly-chirped grating is stretched, the time delay curve is shifted toward longer wavelengths, but the slope of the ps-vs.-nm curve at a specific channel wavelength changes continuously. Ultimately, tunable dispersion compensators should accommodate multichannel operation. Several WDM channels can be accommodated by a single chirped FBG in one of two ways: fabricating a much longer (i.e., meters-length) grating, or using a sampling function when writing the grating, thereby creating many replicas of transfer function of the FBG in the wavelength domain (see Fig. 16).

One free-space-based tunable dispersion compensation device is the virtually imaged phased array (VIPA), based on the dispersion of a Fabry–Perot interferometer. The design requires several lenses, a movable mirror (for tunability), and a glass plate with a thin film layer of tapered reflectivity for good mode matching. Light incident on the glass plate undergoes several reflections inside the plate. As a result, the beam is imaged at several virtual locations, with a spatial distribution that is wavelength-dependent.

Several devices used for dispersion compensation can be integrated on a chip, using either an optical chip media (semiconductor-based laser or amplifier medium) or an electronic chip. One such technology is the micro-ring resonator, a device that, when used in a structure similar to that of an all-pass filter (see Fig. 17), can be used for dispersion compensation on a chip-scale. Although these technologies are not yet ready for deployment as dispersion compensators, they have been used in other applications and have the potential to offer very high performance at low cost.

Fig. 15 Tuning results for both linearly and nonlinearly chirped FBGs using uniform stretching elements. The slope of the dispersion curve at a given wavelength λ_0 is constant when the linearly chirped grating is stretched, but changes as the nonlinearly chirped grating is stretched.

Fig. 16 The concept of 'sampled' FBGs, where a superstructure is written on top of the grating that produces a Fourier transform in the frequency domain, leading to multiple grating passbands.

Fig. 17 Architecture of an all-pass filter structure for chromatic dispersion and slope compensation. Reproduced with permission from Madsen CK, Lenz G, Bruce AJ, *et al.* (1999) Integrated all-pass filters for tunable dispersion and dispersion slope compensation. *Photon. Technol. Lett.* 11 (12): 1623–1625.

As the ultimate optical dispersion compensation devices, photonic bandgap fibers (holey fibers) are an interesting class in themselves (see Fig. 18). These are fibers with a hollow structure, with holes engineered to achieve a particular functionality. Instead of being drawn from a solid preform, holey fibers are drawn from a group of capillary tubes fused together. This way, the dispersion, dispersion slope, the nonlinear coefficients could in principle all be precisely designed and controlled, up to very small or very large values, well outside the range of those of the solid fiber.

Dispersion Slope Mismatch

Transmission fiber, especially fiber with dispersion compensation built in, may suffer from a dispersion slope in which a slightly different dispersion value is produced for each WDM channel (see Fig. 19). Even though the compensator would be able to cancel

Fig. 18 (a) SEM image of a photonic crystal fiber (holey fiber), and (b) net dispersion of the fiber at 1550 nm as a function of the core diameter. Lett.* 11(6): 674–676.

Fig. 19 The chromatic dispersion slope mismatch caused by the different slopes of transmission fiber (SMF or NZDSF) and DCF.

the dispersion of the fiber at the design wavelength, there will be residual dispersion left at the other wavelength channels unless the compensator can match the slope of the dispersion curve of the fiber as well. Some solutions for dispersion slope compensation are described in this section.

First, DCF, with negative dispersion slope, is a prime candidate for deployment as a dispersion slope compensator even though it cannot easily be made tunable. By designing the DCF with the same ratio of dispersion to dispersion slope as that of a real fiber link, new types of DCF can be used to compensate for both dispersion and dispersion slope, much like DCF is used for dispersion compensation today. DCF's popularity, wideband functionality, and stable dispersion characteristics make this a particularly attractive solution. Designing the DCF to match the dispersion characteristics of the transmission fiber is the critical engineering challenge in this slope compensation scheme. Second, third-order nonlinearly chirped FBG can act as a tunable dispersion slope compensator. A simple modification of the nonlinearly chirped FBG allows tuning of the compensated dispersion slope value via stretching the grating. The grating is prepared such that the time delay as a function of wavelength has a cubic profile that covers several WDM channels over a continuous bandwidth of many nanometers. Since the resulting dispersion curve is quadratic over the grating bandwidth, the dispersion slope experienced by the WDM channels can be tuned by stretching the grating using a single mechanical element (see Fig. 20). Third, combining the VIPA, with either a 3D mirror or diffraction grating, can also provide tunable free-space dispersion slope compensation. Slope tuning is achieved by dynamically controlling the MEMS-based 3D mirror or the diffraction grating. Fourthly, using an FBG with many spaced thin-film heater sections can also enable tunable dispersion slope. Each heater can be individually electrically controlled, allowing the time delay profile of the grating to be dynamically tuned via changing the temperature along the length of the grating. Advanced applications of this technique can allow alterations to the entire time delay profile of the grating, providing a truly flexible dispersion and dispersion slope compensation mechanism.

Chromatic Dispersion Monitoring

Another important issue related to dispersion management is dispersion monitoring techniques. In a reconfigurable system, it is necessary to reconfigure any tunable chromatic dispersion compensation modules on the fly as the network changes. An in-line chromatic dispersion monitor can quickly measure the required dispersion compensation value while data are still being transmitted through the optical link. This is very different from the more traditional chromatic dispersion measurement techniques where dark fiber is used and the measurement is done off-line over many hours (or days).

Chromatic dispersion monitoring is most often done at the receiving end, where the Q-factor of the received data or some other means is employed to assess the accumulated dispersion. Existing techniques that can monitor dispersion in-line, fast, and with relatively low cost include: (i) general performance monitoring using the bit-error rate (BER) or eye opening, but this approach cannot differentiate among different degrading effects; (ii) detecting the intensity modulation induced by phase modulation at the transmitter; (iii) extracting the bit-rate frequency component (clock) from photo-detected data and monitoring its RF power (see Fig. 21); (iv) inserting a subcarrier at the transmitter and subsequently monitoring the subcarrier power degradation;

(v) extracting several frequency components from the optical data using very narrow-band optical filters and detecting the optical phase; (vi) dithering the optical-carrier frequency at the transmitter and measuring the resultant phase modulation of the clock extracted at receiver with an additional phase-locked loop; and (vii) using an optical filter to select the upper and lower vestigial sideband (VSB) signals in transmitted optical data and determine the relative group delay caused by dispersion (see [Fig. 22](#)).

Conclusion

Chromatic dispersion is a phenomenon with profound implications for optical fiber communications systems. It has negative effects, broadening data pulses, but it also helps reduce the effects of fiber nonlinearities. For this reason, managing dispersion, rather than trying to eliminate it altogether, is the key. Fixed dispersion components are suitable for point-to-point OC-192 systems. Tunable dispersion components are essential for dispersion management in reconfigurable and OC-768 systems. These dispersion compensation elements must have low loss, low nonlinearity, and must be cost effective.

Although several technologies have emerged that meet some or all of the above requirements, no technology is a clear winner. The trend is towards tunable devices, or even actively self-tunable compensators, and such devices will allow system designers to cope with the shrinking system margins and with the emerging rapidly reconfigurable optical networks.

Introduction

The ever-increasing aggregate demand of electrically based time division multiplexing systems should have coped with the steady growth rate of voice traffic. However, since 1990, the explosive growth of the Internet and other bandwidth-demanding multimedia applications, has meant that long-haul telecommunication traffic has been increasingly dominated by data, not voice traffic. Such systems suffer from a bandwidth bottleneck due to speed limitations of the electronics. This limits the maximum data rate to considerably less than the THz bandwidth offered by an optical fiber. Optical technology is proposed as the only viable option and is expected to play an ever increasing role in future ultrahigh-speed links/networks. There are a number of multiplexing techniques, such as space division multiplexing (SDM), wavelength division multiplexing (WDM), and optical time division multiplexing (OTDM), that are currently being applied to effectively utilize the bandwidth of optical fiber as a means to overcome the bandwidth bottleneck imposed by electrical time division multiplexing (TDM). In SDM a separate optical fiber is allocated to each channel, but this is the least preferred option for increasing channel numbers. In WDM, a number of different data channels are allocated to discrete optical wavelengths for transmission over a single fiber. Dense WDM technology has been improving at a steady rate in recent years, with the latest systems capable of operating at a data rate of > 1 T bps, using a large number of wavelengths over a single fiber link. However, there are a number of problems associated with the WDM systems such as:

- Performance of WDM is highly dependent on the nonlinearities associated with fiber, i.e.:
 - *Stimulated Raman scattering*: degrades the signal-to-noise (SNR) as the number of channels increases;
 - *Four-wave mixing*: limits the channel spacing;
 - *Cross-phase modulation*: limits the number of channels.
- Relatively static optical paths, thus offering no fast switching with high performance within the network;
- Switching is normally carried out by separating each wavelength of each fiber onto different physical outputs. Space switches are then used to spatially switch the separated wavelengths, an extremely inefficient way of utilizing network resources;
- The need for amplifiers with high gain and flat spectra.

In order to overcome these problems, OTDM was introduced that offers the following:

- Flexible high bandwidth on demand (> 1 Tbit/s compared to the bit rates of 2.5–40 Gbit/s per wavelength channel in WDM systems);
- The total bandwidth offered by a single channel network is equal to DWDM;

- In a network environment, OTDM provides potential improvements in:
 - Network user access time, delay and throughput, depending on the user rates and statistics.
 - Less complex end node equipment (single-channel versus multichannels).
- Self-routing and self-clocking characteristics;
- Can operate at second- and third-transmission windows:
 - 1500 nm (like WDM) due to Erbium doped fiber amplifier (EDFA);
 - 1300 nm wavelengths.
- Offers both broadcast and switched based networks.

Principle of OTDM

Fig. 1 show the generic block diagram of a point-to-point OTDM transmission link, where N optical data channels, each of capacity M Gbps, are multiplexed to give an aggregate rate of $N \times M$ Gbps. The fundamental components are a pulsed light source, an optical modulator, a multiplexer, channel, add/drop unit, and a demultiplexer. The light source needs to have good stabilities and be capable of generating ultrashort pulses (< 1 ps). Direct modulation of the laser source is possible but the preferred method is based on external modulation where the optical signal is gated by the electronic data. The combination of these techniques allows the time division multiplexed data to be encoded inside a subnanosecond time slot, which is subsequently interleaved into a frame format. Add/drop units provide added versatility (see Fig. 2) allowing the 'adding' and 'dropping' of selected OTDM channels to interchange data at chosen points on the link. At the receiving end, the OTDM pulse stream is demultiplexed down to the individual channels at the initial M Gbps data rate. Data retrieval is then within the realm of electronic devices and the distinction between electronic and optical methods is no longer relevant. Demultiplexing requires high-speed all optical switching and can be achieved using a number of methods, which will be discussed in more detail below.

The optical multiplexing (or interleaving) can be carried out at the bit level (known as bit interleaving) or at the packet level (known as packet interleaving), where blocks of bits are interleaved sequentially. This is in accord with the popular conception of packet switched networks. The high data rates required and consequently narrow time slots necessitate the need for strict tolerances at processing nodes, e.g., switches. As such, it is important that the duration of the optical pulses is chosen to be significantly shorter than the bit period of the highest multiplexed line rate, in order to reduce the crosstalk between channels.

Fig. 1 Block diagram of a typical OTDM transmission system.

Fig. 2 Add/drop unit in an OTDM network node.

Bit Interleaved OTDM

A simple conceptual description of a bit interleaved multiplexer is shown in Fig. 3. It uses a number of different length optical fiber delay lines (FDL) to interleave the channels. The propagation delay of each FDL is chosen to position the optical channel in its corresponding time slot in relation to the aggregate OTDM signal. Prior to this, each optical pulse train is modulated by the data stream. The output of the modulators and an undelayed pulse train, labeled the framing signal, are combined, using a star coupler or combiner, to produce the high bit rate OTDM signal (see Fig. 3(b)). As shown in Fig. 3(b), the framing pulse has a higher intensity for clock recovery purpose. At the demultiplexer, the incoming OTDM pulse train is split into two paths (see Fig. 4(a)). The lower path is used to recover the framing pulse by means of thresholding, this is then delayed by an amount corresponding to the position of the i th (wanted) channel (see Fig. 4(b)). The delayed framing pulse and the OTDM pulse stream are then passed through an AND gate to recover the i th channel. The AND operation can be carried out all optically using, for example, a nonlinear loop mirror, a terahertz optical asymmetric demultiplexer, or a soliton-trapping gate.

Fig. 3 Bit interleaved OTDM; (a) block diagram and (b) timing waveforms.

Fig. 4 Bit interleaving demultiplexer: (a) block diagram and (b) typical waveforms.

Packet Interleaved OTDM

Fig. 5(a) shows the block diagram of a system used to demonstrate packet interleaving. Note that the time interval between successive pulses now needs to be much less than the bit interval T . This is achieved by passing the low bit rate output packet of the modulator into a compressor, which is based on a feed forward delay line structure. The feed forward delay lines are based on a cascade of passive M-Z interferometers with unequal arm lengths. This configuration generates the delay times required, i.e., $T - \tau, 2(T - \tau) \dots (2^{n-1})(T - \tau)$, etc., where $n = \log_2 k$ is the number of stages, T and τ are the incoming bit duration and the outgoing bit duration, respectively, and k is the packet length in bits. Pulse i 's location at the output is given by $(2^n - 1)(T - \tau) + (i - 1)\tau$. The signal at the input of the compressor is:

$$I_{in}(t) = \sum_{i=0}^{k-1} \delta(t - iT) A_i \quad (1)$$

Where $\delta(\cdot)$ is the optical carrier pulse shape, and A_i is the i th data bit in the packet.

As shown in Fig. 5(b), each bit is split, delayed, and combined to produce the four bit packets O_i :

$$O_i(t) = \frac{1}{2^{n+1}} \sum_{i=0}^{k-1} I_i[t - i(T - \tau)] \quad (2)$$

Note the factor of $1/(2^{n-1})$ is due to the signal splitting at the 2×2 3-dB coupler at the input of each stage.

The combined signal is shown in Fig. 5(b), and is defined as:

$$I_{out} = \sum_{i=0}^{k-1} O_i = \frac{1}{2^{n+1}} \sum_{i=0}^{k-1} \sum_{j=0}^{k-1} I_i[t - (i+j)T + j\tau] A_i \quad (3)$$

For a packet delay of $(i+j)T$ packets are being built up. For the case $(i+j=3)$, four bits are compressed into a packet (see Fig. 5(b)). An optical gating device is used to select the only complete usable compressed copy of the incoming packets from the unwanted copies.

Fig. 5 Packet interleaving multiplexer: (a) block diagram and (b) typical waveforms.

Fig. 6 Packet interleaving demultiplexer: (a) block diagram and (b) typical waveforms.

At the receiving end, demultiplexing is carried out by decompressing the OTDM packet stream using the same delay line structure (see Fig. 6). Multiple copies of the compressed packet are generated, and each is delayed by $(T-\tau)$. An optical demultiplexer placed at the output of the delay lines generates a sequence of switching window at the rate of $1/T$. By positioning the switching pulses at the appropriate position, a series of adjacent packet (channel) bits from each of the copied compressed packets is extracted (see Fig. 6(b)). The output of the demultiplexer is the decompressed packet signal, which can now be processed at a much slower rate using electronic circuitry.

Components of an OTDM System

Optical Sources

In an ultrahigh speed OTDM system, it is essential that the optical sources are capable of generating transform-limited sub-nanosecond pulses having low duty cycles, tuneability, and a controllable repetition rate for synchronization. A number of suitable light sources are: gain-switch distribute feedback laser (DFB), active mode locked lasers (MLL) (capable of generating repetitive optical pulses), and harmonic mode-locking Erbium-doped fiber (EDF) lasers. Alternative techniques include super-continuum pulse generation in a dispersion shifted fiber with EDF pumping, adiabatic soliton compression using dispersion-flattened dispersion decreasing fiber, and pedestal reduction of compressed pulses using a dispersion-imbalanced nonlinear optical loop mirror. As shown in Fig. 1, the laser light source is power split to form the pulse source for each channel. These are subsequently modulated with an electrical data signal (external modulation). External modulation is preferred in an OTDM system as it can achieve narrow carrier linewidth, thus reducing the timing jitter of the transmitted pulse. For ultrahigh bit rate OTDM systems, the optical pulses emerging from the external modulators may also need compressing. One option is to frequency-chirp the pulses and pass them through an anomalous dispersive medium. Using this approach, it is essential that the frequency chirp be linear throughout the duration of the pulse, in addition the midpoint of the linear-frequency chirp should coincide with the center of the pulse. When a frequency-chirped pulse passes through a dispersive medium, different parts of the pulse travel at different speeds, due to a temporal variation of frequency. If the trailing edge travels faster than the leading edge, the result would be pulse compression. An optical fiber cable or a semiconductor laser amplifier (SLA) can be used to create the frequency chirp.

Multiplexers

Multiplexing of the pulses generated by the optical sources can be implemented either passively or actively. The former method is commonly implemented using a mono-mode optical fiber. This method has the advantage of being simple and cost-effective. The latter method uses devices more complex in nature, for example, electro-optic sampling switches, semiconductor optical amplifiers, and integrated optics.

Fig. 8 Electro-optics demultiplexer and receiver system block diagram.

An integrated active multiplexer can be made by integrating semiconductor laser amplifiers (SOA) into a hybrid planar light-wave circuit (PLC). If the optical path length is kept short then temperature control is made easier. An alternative to this approach is to use lithium niobate (LiNb) technology. Periodically poled LiNb (PPLN) based OTDM multiplexers offer compact size and low noise (due to the absence of amplifier spontaneous emission noise and pattern effect, which is a feature of SOA based devices). **Fig. 7** is a schematic of a PLC-based OTDM multiplexer composed of two PLCs (R and L), composed of 1×8 and 8×1 couplers, eight 2×1 couplers, and eight different path length PPLN waveguides. The input clock pulse is split into eight by the 1×8 coupler in PLC-L, and are combined with the modulated optical pulse trains using the 2×1 couplers. The outputs of the 2×1 couplers are then passed through a PPLN waveguide to generate a return-to-zero (RZ) optically modulated signal. These are then combined, using the 8×1 coupler in PLC-R. When the path-length difference between the waveguides is set to one time slot (equal to $1/8$ of the base data rate), then the output of the 8×1 coupler is the required high-bit rate OTDM pulse.

Demultiplexers

In contrast to multiplexing, demultiplexing must be performed as an active function. It can be implemented electro-optically or optically. The former method needs to complete demultiplexing of all channels in order to extract a single channel (see **Fig. 8**). The demultiplexer in **Fig. 8** uses two LiNb Mach-Zehnder (M-Z) modulators in tandem. The first and second modulators are driven with a sinusoidal signal of amplitudes $2V_\pi$ and V_π , respectively, to down-convert the N -bit rate to $N/2$ and $N/4$, respectively. Channels can be selected by changing either the DC-bias $V+$ to the M-Zs, or the electrical phase delay. At ultrahigh speed

implementation of an electro-optics demultiplexer becomes increasingly difficult due to the higher drive voltage requirement by the M-Z. An alternative is to use all optical demultiplexing based on the nonlinear effect in a fiber and optical active devices offering switching resolution in the order of picoseconds. There are a number of methods available to implement all optical demultiplexing. The most popular methods that use fast phase modulation of an optical signal are based on M-Z and Sagnac interferometers. Four-wave mixing is another popular method.

Mach-Zehnder (M-Z) Interferometers

The key to interferometric switching is the selection of an appropriate material for the phase modulation. Semiconductor materials, often in the form of an SLA, are suitable devices for this purpose. The refractive index of an SLA is a function of the semiconductor carrier density, which can be modulated optically resulting in fast modulation. If a high-intensity pulse is input to an SLA the carrier density changes nonlinearly, as shown in Fig. 9. Phase modulation is affected via the material chirp index (dN/dn), which represents the gradient of the refractive index carrier density curve for the material. The phase modulation is quite strong and, in contrast to the intensity-based nonlinearity in an optical fiber, (see Kerr effect below), is a consequence of a resonant interaction between the optical signal and the material. The nonlinearity is relatively long-lived and would be expected to limit the switching speed when using semiconductors. Semiconductors, when in excitation from an optical field, tend to experience the effect quite quickly (ps) with a slow release (hundreds of picoseconds) time. Advantage can be taken of this property by allowing the slow recovery to occur during the time between channels of an OTDM signal, as this time may be of the order of hundreds of pico-seconds or more. A Mach-Zehnder configuration using two SLAs, one in each arm of the interferometer placed asymmetrically, is shown in Fig. 10. An optical control pulse entering the device via port 3 initiates the nonlinearity. The transmission equation relating the input signal (port 1) to the output port is given by

$$\frac{I_{out}(t)}{I_{in}(t)} = 0.25(G_{SLA1}(t) + G_{SLA2}(t) \pm 2\sqrt{G_{SLA1}(t)G_{SLA2}(t)}\cos\Delta\phi(t)) \quad (4)$$

where $G_{SLA1}(t)$ and $G_{SLA2}(t)$ refer to the gain profiles of the respective SLAs, and $\Delta\phi(t)$ is the time-dependent phase difference between them. Assuming that the gain and phase profiles of an excited amplifier are given by $G(t)$ and $\phi(t)$, respectively, then the

Fig. 9 SLA carrier density response to input pulse.

Fig. 10 Asymmetric TWSLA Mach-Zehnder devices.

signals passing through the upper and lower arms experience optical properties of the material given by:

$$G(t), G(t - T_d), \phi(t) \text{ and } \phi(t - T_d) \quad (5)$$

where T_d is given by $2L_d N_{SLA}/c$, L_d is the distance between SLA1 and SLA2, N_{SLA} is the SLA index, and c is the speed of light in a vacuum. As the width of the $\Delta\phi(t)$ profile is dependent on the distance between the SLAs, placing them in close proximity allows high-resolution switching. Less emphasis has been placed on the SLA gain as this is considered to be less effective when phase differences of π are reached. It only remains for the gain and phase modulation to recover, and as indicated previously, this is allowable over a time-scale commensurate with tributary rates.

Sagnac Interferometers

There are two main types; the nonlinear optical loop mirror (NOLM), and the terahertz optical asymmetric demultiplexer (TOAD).

NOLM

In this method of switching the inherent nonlinearity of an optical fiber known as the Kerr effect is used. The phase velocity of any light beam passing through the fiber will be affected by its own intensity and the intensity of any other beams present. When the intrinsic third-order nonlinearity of silica fibers is considered via the intensity-dependent nonlinear refraction component, then the signal phase shift is

$$\Delta\phi_{\text{signal}} = \frac{2\pi}{\lambda_{ds}} n_2 L I_{ds} + 2 \frac{2\pi}{\lambda_{ds}} n_2 L I_c \quad (6)$$

where n_2 is the Kerr coefficient, I_{ds} is the intensity of the data signal to be switched, I_c is the intensity of the control signal used to switch the data signal, λ_{ds} is the data signal wavelength, and L is the fiber length. The optical loop mirror consists of a long length of mono-mode fiber formed into a fiber coupler at its free ends (see Fig. 11). The input to the loop comprises the high-frequency data stream plus a control pulse at the frame rate. The data split at the coupler and propagate around the loop in contra directions (clockwise E_{CW} and counter-clockwise E_{CCW}) recombining back at the coupler. In the absence of a control pulse, the pulse exits via port 1. If a particular pulse in the loop (in this example E_{CW}) is straddled by the control pulse (see Fig. 12), then that pulse experiences cross-phase modulation, according to the second term on the right-hand side of Eq. (6), and undergoes a phase change relative to E_{CW} . The difference in the phase between E_{CW} and E_{CCW} causes the pulse to exit via port 2. The phase shift profile experienced by the co-propagating pulse is

$$\Delta\phi(t) = \frac{4\pi}{\lambda_{ds}} n_2 \int_0^L I_c(t) dx \quad (7)$$

Assuming unity gain around the loop, the transmittance of the NOLM is

$$T_x = 1 - \cos^2\left(\frac{\Delta\phi}{2}\right) = \Delta\phi(t) = 1 - \cos^2\left(\frac{2\pi}{\lambda_{ds}} n_2 \int_0^L I_c(t) dx\right) \quad (8)$$

As it stands, the switching resolution is determined by the width of the control pulse; however, it is possible to allow the signal and control to 'walk off' each other, allowing the window width to be increased by an amount determined by the 'walk off'. The phase shift is now

$$\Delta\phi(t) = 2 \frac{2\pi}{\lambda_{ds}} n_2 \int_0^L I_c(t - T_w x) dx \quad (9)$$

Fig. 11 Nonlinear optical loop mirror.

Fig. 12 Control and data pulses propagation in the fiber.

Fig. 13 Transmittance profiles with the walk-off time as a parameter.

where the parameter T_w is the walk off time per unit length between control and signal pulses. The increased window width is accompanied by a lower peak transmission (see Fig. 13).

TOAD

The TOAD uses a loop mirror architecture that incorporates an SLA and only needs a short length of fiber loop (see Fig. 14(a)). The SLA carrier density is modulated by a high-intensity control pulse, as in the M-Z-based demultiplexer. The operation of the TOAD is similar to the NOLM, where the loop transmittance is determined by the phase difference between CW and CCW traveling pulses. Strictly speaking, the gain of the SLA must also be taken into account; however, without any loss of generality the effect is adequately described by considering only the phase property. Fig. 14(a) shows the timing diagram associated with a TOAD demultiplexer. The control pulse, shown in Fig. 14(b1), is incident at the SLA at a time t_1 ; the phase profiles for the CCW and CW data pulses are shown in Figs. 14(b2) and (3), respectively. The resulting transmission window is shown in Fig. 14(b4). The window width is given by $t_{asy} = 2\Delta x/c_f$, where Δx is the SLA offset from the loop center and c_f is the speed of light in the fiber. As in NOLM, if the phase difference is of sufficient magnitude, then data can be switched to port 2. The switch definition is, in principle, determined by how close the SLA is placed to the loop center when the asymmetry is relatively large. However, for small asymmetries the switching window is asymmetric, which is due to the CW and CCW gain profiles being different (see Fig. 15). Assuming the phase modulation dominates the transmission then the normalized transmission for a small asymmetry loop is as depicted in Fig. 16. The gain response (not shown) would have a similar shape and temporal position as the phase response.

Four-Wave Mixing (FWM)

FWM demultiplexing uses a concept whereby two optical signals of different wavelengths are mixed together in a nonlinear medium to produce harmonic components. The nonlinearity in this case arises from the third-order nonlinear susceptibility $\chi^{(3)}$ of

Fig. 14 TOAD: (a) architecture and (b) timing diagrams.

Fig. 15 Phase responses for CW and CCW components of TOAD.

an optical fiber, such that the polarization P induced on a pair of electric fields propagating through the fiber is

$$P = \epsilon_0 \chi^{(3)} (E_{ds} + E_c)^3 \quad (10)$$

where ϵ_0 is the vacuum permittivity of the medium, E_{ds} and E_c are the electric fields of data and control signals, respectively. The mixing of the two signals takes place in a long length of fiber in which the control signal propagates alongside the channel to be demultiplexed (see Fig. 17). The control signal is of sufficient intensity to cause the fiber to operate in the nonlinear regime.

Fig. 16 TOAD transmission window profile for small asymmetry loop.

Fig. 17 Block diagram of FWM demultiplexer.

Fig. 18 Four-wave mixing in SOA.

The nonlinear relationship causes a number of frequencies to be generated, with the ones of interest having a frequency given by

$$f_{\text{FWM}} = 2f_c - f_{\text{ds}} \quad (11)$$

An optical filter is then used to demultiplex the required channel from the composite signal. The nonlinearity is detuned from the resonant frequency of the fiber glass and as such tends to be weak, requiring long lengths of fiber to give a measurable effect. The power in the demultiplexed signal, for given data and control signal wavelengths and fiber material, depends on the input power and the fiber length according to

$$P_{\text{FWM}} = kP_{\text{ds}}P_cL_E^2 \quad (12)$$

where k is a constant, P_{ds} is the signal launch power, P_c is the control signal launch power, and L_E is the fiber effective length. FWM is essentially an inefficient method as power is wasted in the unused frequency components of the four-wave signal. More in line with integrated structures, the nonlinear properties of a semiconductor laser amplifier can be used. Here a relatively high-power optical signal is input to the SLA (see Fig. 18). This enables saturation and operation in the nonlinear regime (see Fig. 19). Operating the SLA in saturation allows the nonlinear effects to produce the FWM components as in the fiber method.

Fig. 19 SLA output-input power curve.

Clock and Data Synchronization in OTDM

In common with electronically based TDM systems, clock recovery is fundamental to the recovery of data in ultrahigh-speed OTDM systems. Two main methods are proposed: (i) clock signal transmitted with the OTDM signal (i.e., multiplexed); and (ii) extraction of clock signal from the incoming OTDM pulse stream. In a packet-based system, synchronization between the clock and the data packet is normally achieved by sending a synch pulse with each packet. However, techniques based on optical-phased locked loops are proving popular and remove the need for a separate clocking signal.

Clock Multiplexing

- (i) *Space division multiplexing*: This is conceptually the simplest to implement, where the clock signal is carried on a separate fiber from the data. However, it is susceptible to any differential delay between the different paths taken by clock and data due to temperature variation. It is difficult to justify in systems where the installed fiber base is at a premium.
- (ii) *Wavelength division multiplexing*: Here different wavelengths are allocated to the clock, and payload. It is only really practical for predetermined path lengths between nodes in single-hop networks such as point-point links or broadcast-and-select star networks. It also suffers from random delays between the clock and the payload, which is problematic in an asynchronous packet switched based network, where the optical path length a packet may take is nondeterministic.
- (iii) *Orthogonal polarization*: This is suitable for small links, where separate polarizations are used for the clock and data. However, in large networks it is quite difficult to maintain the polarization throughout the transmission link due to polarization mode dispersion and other nonlinear effects.
- (iv) *Intensity division multiplexing*: This uses higher-intensity optical clock pulses to differentiate it from the data pulses as discussed above. However, in long-distance transmission links, it is difficult to maintain both the clock intensity and its position, due to the fiber nonlinearity.
- (v) *Time division multiplexing*: In this scheme a single clock pulse, which has the same wavelength, polarization, and amplitude as the payload pulses, is separated in time, usually ahead of the data pulses.

Synchronization – Optical Phased Locked Loops (PLL)

The PLL is a common technique used for clock recovery in electronic TDM systems. However, the speed of conventional electronic PLLs tends to be limited by the response of the phase comparators used. There are a number of approaches based on opto-electronic PLL. Opto-electronic PLLs based on four-wave mixing in a traveling wave laser amplifier are complex and can suffer from frequency modulation in the recovered clock. However, others based on balanced photo-detectors, result in low timing jitter and good phase stability. In contrast, a number of all optical methods clock recovery scheme exist, one technique based on the TOAD (see above) is depicted in Fig. 20. The high-speed data stream enters the TOAD at a rate $n \times R$ where n is the number of channels per OTDM frame, and R is the frame rate. A pulse generator, such as a mode locked fiber laser (MLFL) clocked by a local oscillator (LO), is used as the TOAD control input (MLFL-C). The OTDM data is switched by the TOAD at a frequency of say, $R + \Delta f$ Hz. Thus, the switching window samples data pulses at a rate higher or lower than $n \times R$ Hz and uses this signal for cross correlation in the PLL unit. The output of the phase comparator is used to regulate a voltage controlled oscillator (VCO) running at R Hz, which in turn feeds the control signal. The PLL circuit locks into the clock frequency, generating the clock signal $S_c(t)$.

Fig. 20 Ultrafast clock recovery using TOAD.

Fig. 21 Block diagram of OTDM receiver.

OTDM Bit-Error Rate (BER) Performance

Fig. 21 shows a typical block diagram of a high-speed optical receiver for an OTDM system, composed of a NOLM or a TOAD demultiplexer, an optical pre-amplifier, an optical bandpass filter, and a conventional optical receiver using a PIN photodiode. Due to the crosstalk introduced in the demultiplexing process, the demultiplexed optical signal contains not only the target channel but may also contain nontarget channels with reduced amplitude (see the inset in **Fig. 21**). The intensity of the demultiplexed optical signal is boosted by the optical pre-amplifier (EDFA). Amplified spontaneous emission (ASE) from the optical preamplifier adds a wide spectrum of optical fields onto the demultiplexed optical signal. Although an optical bandpass filter (BPF) can reduce the ASE, it still remains one of the major noise sources. The function of the optical filter is to reduce the excess ASE to within the range of the signal spectrum. The PIN photodiode converts the received optical power into an equivalent electrical current, which is then converted to a voltage signal by an electrical amplifier. Finally, the output voltage is sampled periodically by a decision circuit for estimating the correct state (mark/space) of each bit.

The BER performance of an OTDM system deteriorates because of the noise and crosstalk introduced by the demultiplexer and is:

$$\text{BER} = \frac{1}{\sqrt{2\pi}} \frac{\exp(-Q^2/2)}{Q} \quad (13)$$

Fig. 22 BER versus the average received optical power for 100 Gb/s (10 channels) OTDM system.

where Q is defined as:

$$Q = \frac{\bar{I}_m - \bar{I}_s}{\sqrt{\sigma_{\text{RIN},m}^2 + \sigma_{\text{RIN},s}^2 + \sigma_{\text{amp},m}^2 + \sigma_{\text{amp},s}^2 + \sigma_{\text{rec},m}^2 + \sigma_{\text{rec},s}^2}} \quad (14)$$

and $\bar{I}_m$ and $\bar{I}_s$ are the average photocurrents for a mark and a space, respectively. $\sigma_{x,i}$ are the variances of the relative intensity noise (RIN), further optical pre-amplifier and receiver for a mark and a space.

For 100 Gb/s (10 channels) OTDM system, the BER against average received optical power for optimized NOLM and TOAD demultiplexers, is shown in Fig. 22.

Nomenclature

$A(t)$	Full electric field	$S_E(\omega, \tau)$	Spectrogram
$E(t)$	Complex electric field without carrier frequency	$S_E(\Omega, T)$	Sonogram
$E_{\text{sig}}(t, \tau)$	Complex electric field of the FROG trace versus time and time delay	$S(\omega)$	Spectral interferogram
$E_{\text{sig}}(t, \Omega)$	Fourier transform of $E_{\text{sig}}(t, \tau)$ with respect to τ	t, T	Variables for time
$\tilde{E}(\omega)$	Complex electric field in the frequency domain	τ	Fourier transform
$f(t)$	Correlation product	v_g	Group velocity
$f(\omega)$	Fourier transform of the correlation product	$\phi(t)$	Time domain phase
$g(t - \tau)$	Time gate or filter	Δw	Beam waist
G	FROG trace error	Z	Distance metric between the FROG signal field generated by the data constraint and the FROG signal field generated by the mathematical form constraint
$h(\omega - \Omega)$	Frequency gate or filter	Φ	Geometric angle between two beams
$I(t)$	Intensity profile of the electric field in the time domain	$\Delta\phi$	Phase difference
$\tilde{I}(\omega)$	Spectral intensity	$\prod^{(n)}$	n th order nonlinear susceptibility
$I_{\text{FROG}}(\omega, \tau)$	Intensity of the FROG trace	ω	Primary variable for frequency
$\Theta(t)$	Heaviside FUNCTION=0 $t < 0$, =1 $t \geq 0$	$\Delta\omega$	Difference in center frequency between two pulses
$\phi(\omega)$	Frequency domain phase	Ω	Secondary variable for frequency
		$\Omega(t)$	Instantaneous frequency

Introduction

Ultrashort optical pulses have very short time durations, typically less than a few tens of picoseconds. As a result, these pulses are spectrally broad. Because the index of refraction of materials is a function of wavelength, different wavelengths of light travel at different speeds in optical materials, causing the properties of ultrashort optical pulses to change as they propagate. However, the shape of the pulse can influence how the pulse itself interacts with materials. Thus, the goal of ultrafast laser pulse measurement is to obtain not only the intensity profile of the pulse, but also the actual variation of the frequencies that make up the pulse. This is called measuring the intensity and phase of the pulse, respectively.

Even though the development of techniques to characterize ultrashort optical pulses has not been easy, a myriad of pulse measurement techniques have been developed. In this chapter, we will confine our discussion to the most well-known pulse and generally accepted pulse characterization methods in an effort to provide a basic working knowledge of pulse measurement techniques and a fundamental understanding of the principles behind pulse measurement. After a brief discussion of the mathematical representation of ultrashort optical pulses, we will discuss pulse measurement in (roughly) chronological order, starting with autocorrelation methods. The next section introduces a useful method for the measurement of the relative phase between two pulses called spectral interferometry (SI). Following SI, we introduce the notion of the time-frequency representation of ultrashort optical pulses where techniques such as frequency-resolved optical gating (FROG) are discussed. Following the time-frequency section, a relatively new technique known as spectral phase interferometry for direct electric field reconstruction (SPIDER) is discussed.

Mathematical Representation of an Optical Pulse

The time-dependent variations of the pulse are embodied in the pulse electric field, $A(t)$, which can be written:

$$A(t) = \text{Re}[E(t)e^{i\omega_0 t}] \quad (1)$$

where ω_0 is the carrier frequency and Re refers to the real part. While we can use $A(t)$ as it stands for calculations, it is much easier to remove the rapidly varying ω_0 part, $e^{i\omega_0 t}$, and use a slowly varying envelope together with a phase term that contains only the frequency variations, not the rapidly varying carrier frequency:

$$E(t) = [I(t)]^{1/2} e^{i\phi(t)} \quad (2)$$

where $I(t)$ and $\phi(t)$ are the time-dependent intensity and phase of the pulse. (Note that $E(t)$ is complex.) The frequency variation, $\Omega(t)$, is the derivative of $\phi(t)$ with respect to time:

$$\Omega(t) = -d\phi(t)/dt \quad (3)$$

The pulse field can be written equally well in the frequency domain by taking the Fourier transform of Eq. (2):

$$\tilde{E}(\omega) = [\tilde{I}(\omega)]^{1/2} e^{-i\phi(\omega)} \quad (4)$$

where $\tilde{I}(\omega)$ is the spectrum of the pulse, and $\phi(\omega)$ is its phase in the frequency domain. The spectral phase contains time versus frequency information; that is, the derivative of the spectral phase with respect to frequency yields the time arrival of the frequency – the group delay.

Obtaining the intensity and phase, $I(t)$ and $\phi(t)$ (or $\tilde{I}(\omega)$ and $\phi(\omega)$) is called full characterization of the pulse. Common phase distortions include linear chirp, where the phase (either the time domain or frequency domain) is parabolic. When the frequency is increasing in time, the pulse is said to have positive linear chirp; negative linear chirp is when the high frequencies lead the lower frequencies. Higher-order chirps are common, but for these, differentiation between spectral and temporal chirp is required because spectral phase and temporal phase are not interchangeable.

Autocorrelation

Traditionally, we measure events using shorter events. Unfortunately, for the ultrafast researcher, shorter events do not exist and modern electronics are not fast enough. Therefore, because the shortest event we have is the event we wish to measure, traditional pulse measurement methods use the pulse itself to determine the approximate duration of the pulse in question giving birth to the ubiquitous intensity autocorrelation (see Fig. 1). While autocorrelations cannot be used to fully characterize ultrashort optical pulses, the methods used in autocorrelations are fundamental to all pulse measurement schemes.

The intensity autocorrelation is measured by combining a pulse and a delayed replica of a pulse in a nonlinear medium such as a second harmonic generation (SHG) crystal. A pulse is sent onto a beamsplitter to produce the two replicas. One pulse is delayed relative to the other and both are focused together into a SHG crystal. As the delay of one pulse relative to the other is varied, the intensity of the second-harmonic signal is recorded. The intensity autocorrelation is not limited to using SHG; any nonlinearity may be utilized. Indeed, two-photon absorption in a semiconductor LED or photodiode often acts as a convenient nonlinearity. Sometimes a third-order nonlinearity is used to provide some direction of time information about the pulse. When the generation of the signal involves phase matching, such as second harmonic generation, care must be taken to use a thin crystal. Typically, 10 μm to 1 mm thick SHG crystals are used, depending on the bandwidth of the pulse to be measured. The exact thickness depends on the SHG crystal, the pulse width, and the requirements of the measurement.

Regardless of the nonlinearity used, an autocorrelation yields only the approximate duration and shape of the pulse. The structure of the pulse is smeared, producing a smooth, featureless profile for even a complex pulse. Thus, the intensity autocorrelation alone does not determine the intensity profile of the pulse, $I(t)$. Only the interaction of the intensity of the pulse is recorded, producing no phase information for the pulse. Some qualitative information can be gleaned from the spectrum and the autocorrelation, but usually only that the pulse is chirped, and higher-order chirps and complex pulse structures elude such an analysis.

Another useful form of intensity autocorrelation is the single-shot autocorrelator. In this case, fairly large beams are used, and these beams are set to intersect at an angle of 2Φ , tilting the pulse fronts, so that delay is mapped onto a spatial coordinate (see Fig. 2). The beams are then focused into a nonlinear medium using a cylindrical lens. The interaction region in the SHG crystal is imaged onto a linear array or CCD camera. Typically, when second-harmonic generation is used, the SHG crystal is oriented for Type I phase matching. The time window is proportional to $\Delta w(\sin \Phi)/\Delta v_g$, where Δw is the beam waist at the SHG crystal, and v_g is the group velocity of the pulse in the crystal. Like all SHG interactions, care must be exercised to insure that the phase matching is sufficient to mix the entire bandwidth of the pulse.

Jean-Claude Diels improved the intensity autocorrelation by the development of the interferometric autocorrelation. In this configuration, a Michelson interferometer is typically used so that the beams are collinear when arriving at the SHG crystal, which allows the beams to interfere. As a result, fringes appear on the autocorrelation. By examining the shape and extent of the fringes,

Fig. 1 An intensity autocorrelator used to determine the approximate duration of a pulse. The pulse is split into two replicas that are sent into delay lines. The outputs from both delay lines are focused into a doubling crystal. The second harmonic output is monitored as a function of delay between the two pulses. A plot of the signal versus time is the intensity autocorrelation of the pulse.

Fig. 2 A single shot intensity autocorrelator. For this type of autocorrelator, the beam size is large, on the order of 1 cm in diameter, and the pulse fronts are tilted with respect to each other in order to map relative delay to position. The two beams are focused using a cylindrical lens and the output is recorded using an array detector. The inset shows how delay is mapped into position. Inset: the tilted pulse fronts cause time delay to be mapped spatially.

some information about the pulse chirp can be obtained. While this does add to the information provided by an intensity autocorrelation, the added information is only the spectrum of the second harmonic. Unfortunately the addition of the second harmonic spectrum does not provide enough information for full retrieval of the intensity and phase.

Even though autocorrelation alone does not completely determine pulse intensity and phase, it is a very simple and useful technique to determine approximate pulse duration. Sometimes, cross-correlation can be used to determine the duration of a long pulse, if a shorter one is available, or a pulse too weak (or at an inappropriate wavelength) to measure with autocorrelation. The addition of the spectrum and/or the second harmonic spectrum can provide more, albeit, incomplete information about pulse chirp. More importantly, the experimental techniques used by correlation methods are fundamental to all pulse measurement methods.

Spectral Interferometry – Relative Phase Measurements

While determination of the absolute intensity and phase of an ultrashort laser pulse is difficult, determination of the relative phase is not. Invented in the late 1800s, spectral interferometry (SI), measures the relative phase between two pulses. SI, a linear technique, can also be modified (albeit, a some-what complex modification) to be self-referencing for full characterization of the ultrashort optical pulse (See the section on SPIDER below). In addition, when combined with a full pulse characterization technique, SI, because it is a linear technique, provides a method by which very weak optical pulses can be characterized (see below).

Typically, an SI apparatus uses a Mach–Zender interferometer (see Fig. 3). A pulse is split into two replicas; one is sent through a region or medium to measure and the other through a known path. The two pulses remain separated by some known time and are sent, collinearly, into a spectrometer; no time scanning is required. An analysis of the fringe pattern yields the relative phase between the two pulses. In other words, SI provides $\phi_{\text{unk}}(\omega) - \phi_{\text{ref}}(\omega)$, where $\phi_{\text{unk}}(\omega)$ is the unknown pulse phase versus frequency. The spectrum of the two pulses in the frequency domain is

$$\tilde{I}_{\text{SI}}(\omega) = |\tilde{E}_0(\omega) + \tilde{E}_{\text{unk}}(\omega)|^2$$

$$\tilde{I}_{\text{SI}}(\omega) = \tilde{I}_0(\omega) + \tilde{I}_{\text{unk}}(\omega) + 2\sqrt{\tilde{I}_0(\omega)}\sqrt{\tilde{I}_{\text{unk}}(\omega)}\cos(\phi_{\text{unk}}(\omega) - \phi_0(\omega) - \omega\tau) \quad (5)$$

where $\tilde{I}_{\text{SI}}(\omega)$ is the output spectrum, $\tilde{E}_0(\omega)$ is the reference pulse electric field, $\tilde{E}_{\text{unk}}(\omega)$ is the unknown pulse electric field, $\tilde{I}_0(\omega)$ is the reference pulse spectrum, $\tilde{I}_{\text{unk}}(\omega)$ is the unknown pulse spectrum, $\phi_{\text{unk}}(\omega)$ is the unknown pulse phase, $\phi_0(\omega)$ is the reference

Fig. 3 A Mach-Zehnder interferometer is the typical arrangement for spectral interferometry. One path acts as the reference arm and the sample to be measured is placed in the other arm. Unlike standard interferometry, the delay is fixed in a spectral interferometry experiment.

Fig. 4 The steps required for the analysis of spectral interferograms. Part (a) shows a sample SI interferogram. The dominant frequency of the fringes is the delay multiplied by the speed of light. The actual phase differences of interest are the perturbations on this frequency. Part (b) is the Fourier transform of the SI interferogram in Part (a). (Note that this is not the true time domain.) The central peak contains only spectral information. All of the phase information is contained in the satellite peaks. The next step is to mask out the central peak and one of the satellite peaks (Part (c)). The phase of the inverse Fourier transform of Part (c) yields the relative phase between the two pulses (Part (d)).

pulse phase, and τ is the delay between the two pulses. To facilitate extracting the phase difference from the SI output, τ is chosen to yield fringes in the sum spectrum. The spectral fringes, which have a period inversely proportional to the optical path difference between the two beams (see Fig. 4), contain all of the phase difference information.

Fig. 4 shows the steps required to obtain the phase difference between the two pulses. The first step is to subtract out the spectra of the individual pulses in order to isolate the spectral interferogram, $S(\omega)$ (Fig. 4(a)), where

$$S(\omega) = 2\sqrt{I_0(\omega)}\sqrt{I_{\text{unk}}(\omega)}\cos(\phi_{\text{unk}}(\omega) - \phi_0(\omega) - \omega\tau) \quad (6)$$

By Fourier transforming $S(\omega)$, we obtain

$$\mathfrak{F}^{-1}[S(\omega)] = f(t - \tau) + f(-t - \tau) \quad (7)$$

where $f(t)$ is the correlation product between the reference and the unknown electric field (see Fig. 4(b)). The Fourier transform of Eq. (7) multiplied by a Heaviside function, $\theta(t)$ (to remove $f(-t - \tau)$), recovers the amplitude and phase of $f(\omega)$, the Fourier transform of $f(t - \tau)$, which contains the relative spectral phase between the unknown pulse and the unmodified pulse. Some care, however, needs to be taken to correctly remove the linear phase due to the time delay between the two pulses, $\omega\tau$. Also, for best results, the spectrometer should be well calibrated and care should be taken to properly window the spectrum before taking the Fourier transform.

Spectral interferometry is a straightforward and simple technique that always provides a relative phase. For this very reason, care must be taken to make sure the beams are mode-matched as well as collinear; also, interferometric stability must be maintained over the course of the measurement. Furthermore, SI is nongating; that is, CW background in the laser can add to the interferogram, masking transient effects. Nevertheless, spectral interferometry is a useful technique that has been applied to the measurement of the linear and nonlinear spectral phase introduced by optical fibers. More recently, SI has been applied to phase-locking and to phase-resolved pump probe experiments.

Time-Frequency Representation

In 1971, E.B. Treacy laid the foundations for a revolution in pulse measurement by introducing the idea of measuring the intensity versus time for different spectral slices of a pulse. Because his measurements provided both time and frequency information simultaneously, these measurements could be thought of as applying in a hybrid time-frequency domain. At first, this may seem confusing, but similar methods have been used to visualize sounds patterns (a musical score, for example) and speech. A time-frequency plot of this type, where spectral slices of a pulse are plotted versus time, is called a sonogram. The mathematical formalism of a sonogram is:

$$S_E(\Omega, T) = \left| \int_{-\infty}^{\infty} \tilde{E}(\omega) h(\omega - \Omega) e^{-i\omega T} d\omega \right|^2 \quad (8)$$

where $\tilde{E}(\omega)$ is the electric field of the pulse to be measured in the frequency domain and $h(\omega - \Omega)$ is a frequency gate that varies with frequency. The magnitude squared of the inverse Fourier transform of spectral slices yields the sonogram.

In 1991, Chilla and Martinez showed that the sonogram could be used to reconstruct the full intensity and phase of the pulse. That is, under certain conditions, the approximate group delay could be determined as a function of frequency from the sonogram by finding the peak time arrival of each spectral slice; integration of the group delay yields the spectral phase, which together, with the pulse spectrum, provides the intensity and phase of the pulse in the frequency domain. They labelled this technique as frequency domain phase measurement (FDPM).

An experimental diagram of an FDPM apparatus is shown in Fig. 5. The pulse is split into two replicas, and one of the pulse replicas is spectrally filtered. The spectrally filtered pulse is cross-correlated with the original pulse to find the 'time arrival' of the spectrally filtered pulse – defined as the peak of the cross-correlated pulse. Because the spectrally filtered pulse has a much longer time duration than the original pulse, the small perturbation caused by the finite length of the original pulse is neglected.

The main difficulty of the Chilla–Martinez method is that the frequency gate must be very narrow, reducing the filtered pulse energy significantly, which greatly reduces the measured signal strength. If the spectral phase is not well behaved, the filtered pulse may not be much longer than the original pulse. In addition, for a given frequency, the sonogram may have two or more peaks in time, that is, the group delay may not be a function. However, a method called 2D phase retrieval, discussed in the next section, can alleviate many of these issues.

A spectrogram is a relative of the sonogram. Rather than determining the time arrival of spectral slices of a pulse, a spectrogram is obtained when the spectrum of time slices of the pulse are measured. The spectrogram is experimentally much easier to obtain than the sonogram; however, the measured quantity is not quite as mathematically useful as the sonogram because the time slicing of the pulse occurs in the time domain. Thus, if a narrow time gate is used, the time domain phase is obtained. The time domain phase together with the intensity of the pulse, $I(t)$, provides the full intensity and phase of the pulse. Unfortunately, the intensity profile is not as readily measurable as the pulse spectrum. Consequently, to obtain the full intensity and phase of a pulse from its spectrogram requires an iterative 2D phase retrieval algorithm. This is the basis of a pulse measurement technique called frequency-resolved optical gating (FROG).

Fig. 5 Measuring a sonogram requires determining the time arrival of spectral slices of the pulse. The pulse is split into two replicas using a beamsplitter. One replica is spectrally filtered using a tunable filter. The other pulse is cross-correlated with the spectrally filtered pulse to determine the time arrival.

Frequency-Resolved Optical Gating

Frequency-resolved optical gating (FROG), developed by Kane and Trebino, measures the spectrum of a particular temporal component of the pulse (see Figs. 6 and 7) by spectrally resolving the signal pulse in an autocorrelation-type experiment using an instantaneously responding nonlinear medium. As shown in Fig. 6, FROG involves splitting a pulse and then overlapping the two

Fig. 6 Measuring the spectrogram of a pulse is easier than measuring its sonogram – a spectrogram is a spectrally resolved autocorrelation. In this figure, the optical Kerr-effect is used (polarization-gate) as the nonlinearity. Adapted with permission from Kane DJ and Trebino R (1993) Single shot measurement of the intensity and phase of an arbitrary ultrashort pulse by using frequency-resolved optical gating. *Optics Letters* 18(10): 823–825.

Fig. 7 This figure shows a schematic of an SHG FROG device. The SHG signal from the autocorrelation is spectrally resolved. SHG FROG is very simple and sensitive, but it has a direction-of-time ambiguity. For example, if the pulse has chirp, only the magnitude of the chirp is determined – the sign of the chirp remains unknown.

resulting pulses in an instantaneously responding $\chi^{(3)}$ or $\chi^{(2)}$ medium. Even though any instantaneous nonlinear interaction may be used to implement FROG, perhaps the most intuitive is the polarization-gating configuration. In this case, induced birefringence, due to the electronic Kerr effect, is used as the nonlinear-optical process. In other words, the ‘gate’ pulse causes the $\chi^{(3)}$ medium, which is placed between two crossed polarizers, to become slightly birefringent. The polarization of the ‘gated’ probe pulse (which is cleaned up by the first polarizer) is rotated slightly by the induced birefringence allowing some of the ‘gated’ pulse to leak through the second polarizer. This is referred to as the signal. Because most of the signal emanates from the region of temporal overlap between the gate pulse and the probe pulse, the signal pulse contains the frequencies of the ‘gated’ probe pulse within this overlap region. The signal is then spectrally resolved, and the signal intensity is measured as a function of wavelength and delay time τ . The resulting trace of intensity versus delay and frequency is a spectrogram, a time- and frequency-resolved transform that intuitively displays time-dependent spectral information of a waveform.

The spectrogram can be expressed as:

$$S_E(\omega, \tau) = \left| \int_{-\infty}^{\infty} E(t)g(t-\tau)e^{-i\omega t} dt \right|^2 \quad (9)$$

where $E(t)$ is the measured pulse’s electric field, $g(t-\tau)$ is the variable-delay gate pulse, and the subscript E on S_E indicates the spectrogram’s dependence on $E(t)$. The gate pulse $g(t)$ is usually somewhat shorter in length than the pulse to be measured, but not infinitely short. This is an important point: an infinitely short gate pulse yields only the intensity $I(t)$ and conversely, a CW gate pulse yields only the spectrum $I(\omega)$. On the other hand, a finite-length gate pulse yields the spectrum of all of the finite pulse segments with duration equal to that of the gate. While the phase information remains lacking in each of these short-time spectra, having spectra of an infinitely large set of pulse segments compensates for this loss. The spectrogram has been shown to nearly uniquely determine both the intensity $I(t)$ and phase $\varphi(t)$ of the pulse, even if the gate pulse is longer than the pulse to be measured (although if the gate is too long, sensitivity to noise and other practical problems arise).

In FROG, when using optically induced birefringence as the nonlinear effect, the signal pulse is given by:

$$E_{\text{sig}}(t, \tau) \propto E(t)|E(t-\tau)|^2 \quad (10)$$

So the measured signal intensity $I_{\text{FROG}}(\omega, \tau)$, after the spectrometer is:

$$I_{\text{FROG}}(\omega, \tau) = \left| \int_{-\infty}^{\infty} E(t)|E(t-\tau)|^2 e^{-i\omega t} dt \right|^2 \quad (11)$$

We see that the FROG trace is a spectrogram of the pulse $E(t)$ although the gate, $|E(t-\tau)|^2$, is a function of the pulse itself.

To see that the FROG trace essentially uniquely determines $E(t)$ for an arbitrary pulse, it is first necessary to observe that $E(t)$ is easily obtained from $E_{\text{sig}}(t, \tau)$. Then it is simply necessary to write Eq. (11) in terms of $E_{\text{sig}}(t, \Omega)$, the Fourier transform of the signal field $E_{\text{sig}}(t, \Omega)$, with respect to delay variable τ . We then have what appears to be a more complex expression, but one that will give us better insight into the problem:

$$I_{\text{FROG}}(\omega, \tau) = \left| \int_{-\infty}^{\infty} E_{\text{sig}}(t, \Omega) e^{-i\omega t - i\Omega \tau} d\Omega dt \right|^2 \quad (12)$$

Eq. (12) indicates that the problem of inverting the FROG trace $I_{\text{FROG}}(\omega, \tau)$, to find the desired quantity $E_{\text{sig}}(t, \Omega)$, is that of inverting the squared magnitude of the two-dimensional (2D) Fourier transform of $E_{\text{sig}}(t, \Omega)$. This problem, which is called the 2D phase-retrieval problem, is well known in many fields, especially in astronomy, where the squared magnitude of the Fourier transform of a 2D image is often measured. At first glance, this problem appears unsolvable; after all, much information is lost when the magnitude is taken. It is well known that the one-dimensional (1D) phase retrieval problem is unsolvable (for example, infinitely many pulse fields give rise to the same spectrum). Intuition fails in this case, however; two- and higher-dimensional phase retrieval essentially always yields unique results.

The Simplified FROG – GRENOUILLE

A simplified version of the FROG device, known as grating eliminated no-nonsense observation of ultrafast incident laser light e-fields (GRENOUILLE), can be constructed using the doubling crystal as both the gating medium and the spectrometer (see Fig. 8). In this case, the phase matching condition in certain thick doubling crystals causes a wavelength dependent output from the doubling crystal. A cylindrical lens is used in a Fourier transform configuration to image the wavelength variation onto a CCD camera. A cylindrical lens set at 90 degrees to the Fourier transform lens images the time axis onto the CCD camera. A Fresnel biprism replaces the traditionally used Mach-Zender interferometer to produce two pulses propagating at an angle with respect to each other. Presently, the GRENOUILLE technique works with BBO, in the wavelength region around 500 nm–1200 nm, and with proustite in the wavelength region around 1200 nm–2000 nm.

Fig. 8 Fig. showing a schematic of a GRENOUILLE FROG device which uses a thick doubling crystal as both the gating nonlinearity and the spectrometer. Like single-shot autocorrelators, a cylindrical lens focuses a spatially large input beam into an SHG crystal in only one dimension. Unlike most autocorrelators, the Mach–Zender interferometer is replaced with a Fresnel biprism that forces each half of the input beam to propagate, at an angle, toward the SHG crystal. An imaging cylindrical lens images the spatial dependence of the delay onto a CCD camera. A Fourier transform cylindrical lens maps the angular dependence of wavelength from the SHG crystal to a spatial coordinate on the CCD camera. FROG Inversion Algorithms

An iterative 2D phase retrieval algorithm is required to extract the pulse information from the measured FROG trace (see Figs. 9 and 10). This algorithm converges to a pulse that minimizes the difference between the measured and the calculated FROG trace. While this aspect of FROG has been its Achilles heel in the past, in reality, new generalized projections algorithms (together with faster computers) converge quickly and can track pulse changes at rates up to 30 Hz and beyond, making FROG a true, real-time pulse measurement technique. Indeed, excellent algorithms for the analysis of FROG traces in real-time are commercially available.

The original FROG inversion algorithm, commonly referred to as the vanilla algorithm, is simple and iterates quickly, but tends to stagnate, giving erroneous results, especially for geometries that use a complex gate function such as SHG or self-diffraction. An improved algorithm, incorporating several different algorithms including brute force minimization, was developed to alleviate stagnation programs at the expense of both speed and convergence time. By the mid-1990s, a significant advance in both speed and stability was made by the addition of a numerical method called generalized projections. This algorithm determines the next guess by constructing a projection – minimizing the error (distance) between the FROG electric field, $E_{\text{sig}}(t, \tau)$, obtained immediately after the application of the intensity constraint, and the FROG electric field calculated from the mathematical form constraint.

The first generalized projections algorithm used a standard minimization procedure to find the electric field for the next iteration, which can still be slow. For the most common FROG geometries, PG and SHG, a different algorithm that determines the next iteration directly has been developed. This algorithm, called the principal components generalized projections (PCGP) algorithm, converts the generalized projections algorithm into an eigenvector problem. Using this algorithm, pulse measurement rates of at least 30 Hz have been achieved.

The goal of the phase retrieval algorithm is to find the $E(t)$ that satisfies two constraints. The first is the FROG trace itself which is the magnitude squared of the 1D Fourier transform of $E_{\text{sig}}(t, \tau)$:

$$I_{\text{FROG}}(\omega, \tau) = \left| \int_{-\infty}^{\infty} E_{\text{sig}}(t, \tau) e^{-i\omega t} dt \right|^2 \quad (13)$$

The other constraint is the mathematical form of the signal field, $E_{\text{sig}}(t, \tau)$, for the nonlinear interaction used. The signal forms for a variety of FROG beam geometries are:

$$E_{\text{sig}}(t, \tau) \propto \begin{cases} E(t)|E(t-\tau)|^2 & \text{PG FROG} \\ E(t)^2 E^*(t-\tau) & \text{SD FROG} \\ E(t)E(t-\tau) & \text{SHG FROG} \\ E(t)^2 E(t-\tau) & \text{THG FROG} \end{cases} \quad (14)$$

where PG is polarization gate, SD is self-diffraction, SHG is second harmonic generation, and THG is third harmonic generation FROG.

Fig. 9 Example FROG traces and sonograms are shown for four different pulses: a transform limited pulse, a positively chirped pulse, and a negatively chirped pulse. The top series of plots are the time domain representation of the pulse intensity (solid line) and phase (dashed line). The second row of four plots is the frequency domain representation of the sample pulse's intensity and phase. The next four plots show the instantaneous frequency and the group delay. The vertical axis is frequency and the horizontal axis is time. The remaining rows show the PG FROG traces, the SHG FROG traces and sonograms of the pulse shown in the first two rows.

Fig. 10 Phase retrieval algorithm for the inversion of FROG spectrograms. Start with an initial guess for the pulse to generate an initial $E_{\text{sig}}(t, \tau)$. A 1D Fourier transform generates the FROG trace. The next step is to replace the magnitude of the calculated FROG trace with the square root of the measured FROG trace. Inverse Fourier transform with respect to ω to produce the new signal field and generate a new guess for $E(t)$. Interestingly, it is only the step that produces $E(t)$ from $E_{\text{sig}}(t, \tau)$ that differentiates all the FROG algorithms.

All FROG algorithms work by iterating between two different data sets: the set of all signal fields that satisfy the data constraint, $I_{\text{FROG}}(\omega, \tau)$, and the set of all signal fields that satisfy Eq. (14). The difference between the FROG algorithms is how the iteration between the two sets is completed. In the case of generalized projections, the $E(t)$'s are chosen such that the distance between the $E(t)$ on the magnitude set and the $E(t)$ on the mathematical form set is minimized. This is accomplished by minimizing

the following equation:

$$Z = \sum_{i,j=1}^N |E_{\text{sig(DC)}}^{(k)}(t_i, \tau_j) - E_{\text{sig(MF)}}^{(k+1)}(t_i, \tau_j)|^2 \quad (15)$$

where $E_{\text{sig(DC)}}^{(k)}(t_i, \tau_j)$ is the signal field generated by the data constraint, and $E_{\text{sig(MF)}}^{(k+1)}(t_i, \tau_j)$ is the signal field produced from one of the beam geometry equations in Eq. (14). For the normal generalized projection, the minimization of Z is completed using a standard steepest descent algorithm; the derivative of Z with respect to the signal field is computed to determine the direction of the minimum. The computation of the derivatives are tedious; they are tabulated elsewhere.

An alternative to an algorithm that minimizes Eq. (15) is the PCGP algorithm. This algorithm converts the computation of the next guess into an eigenvector problem, reducing the computation of the next guess to simple matrix–vector multiplications. This algorithm works for both the PG and SHG beam geometries, it is robust and the fastest FROG algorithm. Indeed, the PCGP algorithm was used in the original real-time FROG work by D.J. Kane.

Self Checks in FROG Measurements

Unlike any other pulse measurement techniques, FROG can provide a great deal of feedback about both the quality of the measurement (systematic errors) and the quality of the algorithm's performance. The most common check for convergence is the FROG trace error together with a visual comparison between the retrieved FROG trace and the measured FROG trace. The FROG trace error is given by:

$$G = \sqrt{\frac{1}{N^2} \sum_{i,j=1}^N |I_{\text{FROG}}(\omega_i, \tau_j) - \alpha I_{\text{FROG}}^{(k)}(\omega_i, \tau_j)|^2} \quad (16)$$

where α is a renormalization constant, I_{FROG} is the measured trace, and $I_{\text{FROG}}^{(k)}(\omega, \tau)$ is computed from the retrieved electric field. Typically, the FROG trace error of a PG measurement should be less than 2% for a 64×64 pixel trace, while the FROG trace error of a 64×64 pixel SHG FROG trace should be about 1% or less. Acceptable FROG trace errors decrease as FROG trace size increase for smaller FROG traces. These values are only rules of thumb only; for example, acceptable retrievals of large and very complicated FROG traces can produce larger FROG trace errors.

In a good FROG measurement, the spectrum of the retrieved pulse should faithfully reproduce the salient features of the pulse's measured spectrum. SHG FROG even provides an additional check called the frequency marginal. The sum of an SHG FROG trace along the time axis yields the autoconvolution of the pulse's spectrum, providing two ways the FROG measurement can be checked. First, the autoconvolution of an independently measured spectrum can be compared to the sum of the FROG trace along the time axis, providing an indication of how well the measurement was made. For example, if the doubling crystal was too thick in the pulse measurement, the FROG trace's frequency marginal will be narrower than the autoconvolution of the measured spectrum. Second, comparing the autoconvolution of the retrieval pulse spectrum with the FROG trace marginal can provide a test of algorithm convergence in addition to a test of the measurement. Phase matching problems appear as a mismatch between the FROG trace frequency marginal and the autoconvolution of the retrieved spectrum.

Because FROG is a spectrally resolved autocorrelation, summing any FROG trace along the frequency axis yields the autocorrelation of the measured pulse. This autocorrelation can be compared to an independently measured autocorrelation, or a comparison can be made between the frequency sum of the FROG trace and the autocorrelation calculated from the retrieved pulse to determine algorithm convergence and the quality of the measurement.

Measuring Pulses Directly – SPIDER

SPIDER is a novel technique that measures the pulse directly – no iterative phase retrieval method is required. To accomplish this feat, spectral interferometry is conducted on two pulse replicas that are shifted in frequency with respect to one another. The original pulse is split into two replicas. The two pulse replicas are sent into a phase modulator that shifts the center frequency of each pulse slightly. The frequency-shifted pulses are sent into a spectrometer and a standard spectral interferometry analysis yields the derivative of the phase. Integration of the phase derivative, together with the spectrum of pulse, provides the full intensity and phase.

Thus, analysis of the spectral interferogram gives:

$$\Delta\phi = (\phi(\omega_1) - \phi(\omega_2))\Delta\omega \quad (17)$$

where $\Delta\phi$ is the measured phase difference from the spectral interferogram, $\Delta\omega$ is the difference in the center frequency between the two pulses, and $\phi(\omega)$ is the pulse phase as a function of frequency. Consequently, the phase difference must be divided by the frequency difference between the two pulses to determine the true derivative. It is also important to subtract out the linear phase difference resulting from the delay between the two pulses (the delay produces the fringes in the resulting interferogram) as this integrates to a linear chirp.

Fig. 11 Fig. showing how a SPIDER device works. The highly chirped pulse has a frequency that varies with time. Mixing the chirped pulse with two time delayed replicas produces two pulses, separated in time, that have slightly different frequencies, but are otherwise identical. By interfering the two pulses in a spectrometer, the relative phase between $\omega_0 + \delta\omega$ portions of the pulse and ω_0 portions of the pulse are determined.

Fig. 12 SPIDER apparatus. The input pulse is first split into two pulses. One pulse is stretched in a pulse stretcher. The other pulse is sent into a Michelson interferometer to produce two time-delayed pulses. The two time-delayed pulses are mixed with the stretched pulse to produce two pulses at a slightly different center frequency. The two pulses are sent into a spectrometer to produce a spectral interferogram. Analysis of the spectral interferogram yields the derivative of the pulse phase.

Because phase modulators are too slow to be used in the femtosecond region, a different method is used to shift the frequency of the two pulses – they are mixed with a highly chirped pulse (see Fig. 11). Because the pulses are slightly time delayed, each one aligns with a slightly different frequency in the chirped pulse. The chirped pulse must be so highly chirped that the pulse frequency does not change significantly over the duration of the pulse to be measured.

A schematic of a SPIDER device for the measurement of femtosecond laser pulses is shown in Fig. 12. The input pulse is first split into two replicas. The first replica is sent to a pulse stretcher to produce to highly chirped pulse. The other replica is sent into a Michelson interferometer (or a simple étalon may sometimes suffice) to create two time-delayed replicas. The time-delayed replicas are mixed with the chirped pulse. Because each replica is mixed with a slightly different frequency in the chirped pulse, each replica produces a pulse with a slightly different center frequency. When the time-delayed replicas are spectrally resolved, each frequency of the pulse interferes with a frequency-shifted portion of the same pulse. Thus, the measured phase difference is proportional to the derivative of the phase of the original pulse.

Measuring Weak Pulses

Because virtually all the pulse measurement techniques, that do not require a reference pulse, use a nonlinearity, measuring weak ultrafast pulses directly is difficult. Fortunately, because most weak pulses are generated from a stronger pulse, spectral interferometry can be used to determine the relative phase between the weaker pulse and the stronger pulse (for regions where there is spectral overlap between the two pulses). If the stronger pulse is characterized using another pulse measurement technique, then

the weaker pulse phase can be determined from the relative phase measurement and the known phase of the stronger pulse. For example, the Trebino group termed the combination of FROG and SI as TADPOLE (Temporal Analysis by Dispersing a Pair Of Light E-fields).

Which Pulse Measurement Method Should I Use?

Choosing a pulse measurement method depends on the required measurement as well as the precision and accuracy required. All the pulse measurement techniques have advantages and disadvantages, but excellent measurements have been made with all of them. Autocorrelation is adequate when all that is required is the approximate pulse duration without any phase information. Spectral interferometry is quite useful for measuring transient changes in a sample in pump-probe experiments. FROG is perhaps the most commonly used and general-purpose pulse measurement technique, providing a great deal of feedback about the quality of the pulse measurement. Inexpensive and convenient FROG devices, together with software, are available commercially, adding to their acceptance. While SPIDER is experimentally complex and does not have the cross checks that FROG has, it provides the quickest answer, requiring no iterative phase retrieval algorithm to obtain pulse intensity and phase.

Introduction

As the demand for bandwidth continues to grow, driven by the massive increase in Internet usage, so will the necessity to have communications networks that can handle very high data rates. The use of optical fiber networks is the clear choice for such systems given the huge available bandwidth of the fiber transmission medium. However, in a basic optical communication system comprising a laser transmitter, an optical fiber transmission medium, and a receiver, the capacity is essentially limited by the speed at which light can be modulated at the transmitter. To overcome this limitation, which is basically due to the speed of available electronics, it is necessary to use optical multiplexing techniques, and one such technique, known as optical time division multiplexing (OTDM), will be the subject of this article.

Principles of Time Division Multiplexing

Time division multiplexing (TDM) has long been the traditional method for electrically combining information channels. If we take the most fundamental data rate to be that of a simple voice call at 64 kbit/s, then the transmission of data at higher bit rates is achieved by electrically multiplexing a large number of 64 kbit/s channels in the time domain. With the evolution of standards, a number of different data rates have been specified as standard transmission rates. In Europe the synchronous digital hierarchy (SDH) has a basic data rate of 155.52 Mbit/s, which is known as the synchronous transport module – Level 1 (STM-1). This particular data rate is essentially obtained by electrically multiplexing over 2000 voice calls in the time domain (with some of the capacity required for overhead information). By subsequently multiplexing a number of STM-1 channels together we can obtain transmission at the higher standard data rates of STM-4 (622 Mbit/s), STM-16 (2.48 Gbit/s), and STM-64 (9.88 Gbit/s), as outlined in [Table 1](#).

[Fig. 1](#) illustrates how basic electrical TDM is used in standard optical communication systems. Clearly as we approach the higher data rates of STM-64, a serious level of electrical multiplexing is required, and as the data rates increase so does the cost and complexity of the electrical equipment at the transmitter and receiver. Indeed the present state of the art in electronics seems to suggest 40 Gbit/s as the limit for electrically multiplexed communication systems. However, as we stated earlier, communications traffic has been growing explosively over the last decade and will continue to do so. In order to meet this demand for capacity, and better exploit the massive available bandwidth of optical fiber, it is necessary to use optical multiplexing techniques for communications systems. The two main optical multiplexing techniques available are wavelength division multiplexing (WDM) and optical time division multiplexing (OTDM). WDM essentially involves transmitting data at a number of different wavelengths on the same fiber. Although electrical multiplexing may be limited to data transmission rates of around 40 Gbit/s using one laser, by multiplexing together N different wavelength channels each carrying 40 Gbit/s, we can achieve overall data rates up to and beyond a terabit/s.

The second of these optical multiplexing techniques, OTDM, is the subject of this article. Whereas WDM multiplexes optical data channels in the wavelength domain, the basic principle of OTDM communications is to increase the system

capacity by multiplexing optical data channels in the time domain. This multiplexing is usually achieved by a process known as bit-interleaving. This process can be explained by considering Fig. 2, which shows a basic schematic of an OTDM based transmission system. The main component of the overall system is a source of ultrashort optical pulses (pulse duration τ) at a certain repetition rate, R . The optical pulse source is initially split into N channels using a passive fiber coupler, and each pulse train is subsequently modulated by electrical data which is at a data rate of R . The resulting output from each modulator is essentially an optical data channel where the data are represented using ultrashort optical pulses (return-to-zero data format). The data from each modulator then passes through a fixed fiber delay line which delays each channel by a time equal to $1/RN$ relative to its adjacent channel (as shown in Fig. 2). The N modulated and delayed optical data channels are then recombined in another passive fiber coupler to form the OTDM data signal. We can consider that the delay lines essentially assign each data channel to a specific bit slot (of width $1/RN$) in the overall multiplexed signal. The multiplexed data signal may then be transmitted over optical fiber before arriving at the receiver which is responsible for demultiplexing the optical signal into its discrete channels.

The duration of the optical pulse source is extremely important in determining the maximum overall data rate which can be achieved. The overall data rate is basically defined by the temporal separation between channels in the multiplexor, but in order to avoid cross-channel interference, this separation must be significantly greater than the pulse duration. Thus to increase the overall data rate we must use shorter optical pulses. However, as we reduce the optical pulse width to raise the data rate we need to take into account the problems that may be encountered as this high-speed data signal propagates over optical fiber, and also the difficulty in demultiplexing a high-speed OTDM data signal. The following section will look in greater detail at these key elements of the OTDM communication system, namely the optical pulse source, the transmission of the ultrahigh capacity signal, and the demultiplexing at the receiver.

Key Elements of an OTDM Communication System

Ultra-Short Optical Pulse Sources

As stated earlier, the optical pulse source is a key element in any OTDM-based communication system. The important characteristics of the pulse source that will affect its usefulness in an OTDM system are the pulsewidth, the spectral width, and the

temporal jitter. The pulse duration clearly has to be short enough to support the desired overall transmission rate. For example, if we wish to design an OTDM system with an aggregate data rate of 100 Gbit/s (which will have a delay of 10 ps between each channel in the multiplexed signal), then the pulsewidth should normally be less than 30% of the channel spacing to avoid cross-channel interference (i.e. around 3 ps). For terabit/s OTDM systems we would require pulsewidths less than 0.5 ps. The spectral width of the pulse source is also important, as it will have a major impact on how the pulse will evolve during propagation in the fiber. A standard figure of merit which is employed is the time–bandwidth product, and ideally we require the pulse source to be transform limited, which implies that the spectral width is as small as possible for the associated pulsewidth. The impact of temporal jitter on the pulses can be easily understood by considering the above example of a 100 Gbit/s system, employing 3 ps pulses, with the multiplexed channels spaced by 10 ps. Obviously if the jitter on the pulses becomes significant in relation to the channel spacing, then this can also lead to interference between adjacent channels in the overall OTDM system. A large number of techniques have been employed to develop ultrashort pulse sources suitable for use in OTDM systems, but the three main methods which will be described below are active mode-locking, gain-switching, and external modulation of a CW light signal.

Active mode-locking of laser diodes normally involves modulating the amplitude of the optical field inside the laser cavity at a frequency which is equal to the mode spacing of the laser. This can be achieved by applying an electrical sinusoidal signal at the correct frequency, and results in the generation of optical pulses at the repetition rate of the applied signal. This technique has been successfully employed in the generation of subpicosecond pulses at repetition rates up to and beyond 40 GHz, with excellent spectral and temporal jitter characteristics. However, an inherent problem in all mode-locked pulse sources is the difficulty in synchronizing the mode-locked frequency to a specific SDH standard data rate.

Gain switching of semiconductor laser diodes is probably the simplest and most reliable technique to generate optical pulses. The technique, which is presented in Fig. 3, involves applying a high-power electrical pulse (or electrical sinusoidal signal) to the laser in conjunction with a certain bias current. By ensuring that the electrical pulse signal and the bias signal have the correct level, the relaxation oscillation phenomenon of the laser results in the production of optical pulses with durations between 10 and 30 ps, at the repetition rate of the applied electrical signal. The frequency of the electrical signal applied to the laser is essentially arbitrary (provided it is not larger than the modulation bandwidth of the diode), thus making it straightforward to synchronize the optical pulse train to a SDH line-rate. The main problem with this technique is that the spectral width of the pulses generated is such that the pulses are far from transform-limited, which would affect their subsequent propagation in the fiber. In addition, temporal jitter on gain-switched pulses can also be a problem. However, by using novel arrangements such as external injection into the gain-switched laser, this difficulty can be overcome.

The third pulse generation technique mentioned above involves external modulation of a cw light signal with an electro-absorption modulator. The experimental configuration for this pulse generation technique is shown in Fig. 4. By biasing the modulator around its null point, and applying an electrical sinusoidal signal to it, the cw light passing through the modulator becomes shaped into optical pulses. The optical pulse train which is generated due the nonlinear response of the electro-absorption modulator is at a repetition rate of twice the applied electrical signal. The pulses generated are normally transform limited with extremely low temporal jitter, and the repetition rate is arbitrary as in the gain-switching technique (with the limit being ultimately determined by the modulation bandwidth of the modulator). This method may be readily used to generate pulses at repetition rates up to 40 GHz with pulsewidth around 5 ps, and it has the advantage that the optical source and the modulator can be integrated in a single device to form a compact pulse source suitable for OTDM communication systems.

It should also be noted that in addition to the various techniques that have been outlined, it is possible to use pulse compression in order to reduce the pulse width. The main issues concerned with pulse compression are the shape and spectral width of the optical pulses after compression. One of the most attractive methods of achieving pulse compression involves using nonlinear compression in dispersion-decreasing fiber, with the main advantage of this technique being the ability to maintain a transform limited pulse after compression. By employing this compression scheme, optical pulse sources at 10 GHz with pulsewidths below 200 fs have been developed, and such pulsewidths would be suitable for use in Tbit/s OTDM systems.

Fig. 3 Pulse generation using the gain-switching technique followed by pulse compression.

Fig. 4 Pulse generation based on shaping of cw light using the nonlinear response of an external modulator biased about its null point.

Transmission of an OTDM Signal over Fiber

The transmission performance of an OTDM data signal is vital in determining the distance over which the data can be transmitted successfully. The main fiber parameters, which will affect the signal transmission, are attenuation and dispersion. If we consider OTDM systems operating at a wavelength of around 1550 nm (minimum loss wavelength), to overcome the fiber attenuation and maintain a suitable optical power budget for the system, optical amplifiers are normally employed. If we thus assume that the amplifiers overcome the fiber loss problem, then the maximum transmission distance will be limited by the fiber dispersion. In a very basic OTDM system operating at 1550 nm, with transmitter and receiver linked using standard fiber (dispersion parameter of about $16 \text{ ps km}^{-1} \text{ nm}^{-1}$), the maximum transmission distance will be limited by the overall data rate, and the pulsewidth and spectral width of the optical pulse source. For example, consider a 40 Gbit/s OTDM data signal which is formed using 8 ps optical pulses with a spectral width of 40 GHz (0.32 nm). From the spectral width we can calculate the signal broadening due to dispersion to be around 5 ps km^{-1} , and as the pulses broaden and spread into adjacent channels of the OTDM signal then this interference will make it increasingly difficult to correctly detect the signal at the receiver. In this case after propagation through 5 km of fiber, the signal pulses will have already dispersed to around 25 ps duration, the same value as the temporal bit slot into which each channel is placed. This will clearly result in serious loss of signal integrity. A straightforward possibility to increase the transmission distance of OTDM systems is to employ dispersion shifted fiber; the dispersion parameter is now around $1\text{--}2 \text{ ps km}^{-1} \text{ nm}^{-1}$, at an operating wavelength of 1550 nm. This reduction in dispersion will obviously increase the allowed transmission distance by about an order of magnitude for the example described above. However, to develop ultrahigh-speed, long-haul OTDM communications we require more complex transmission schemes. Two possibilities for this include dispersion compensation, and soliton transmission techniques.

Dispersion compensation basically involves compensating for the dispersion that has been encountered during transmission by using some fiber with a total dispersion of opposite sign but equal magnitude to the transmission fiber. Dispersion compensation may also be achieved using a suitably designed fiber grating. For a long-haul OTDM system, a dispersion compensator may be used every 50 or 60 km, in conjunction with the optical amplifier, thus allowing us to compensate both fiber loss and attenuation periodically along the link. The main limitation, however, with the dispersion compensation technique is caused by the dispersion slope of the fiber, as for ideal compensation it is necessary to compensate completely for the dispersion slope in addition to the overall fiber dispersion. The second technique that may be employed to greatly extend the transmission distance of high-speed OTDM communication systems is the use of soliton transmission. The basic principle of soliton transmission is to use optical data pulses with a particular shape, pulsewidth, and peak power, such that as the pulse propagates, the effects of fiber dispersion and nonlinearity counterbalance to allow the signal to propagate undistorted. By using optical amplifiers to ensure that the optical pulse peak power does not vary too much along the transmission link, OTDM transmission at data rates greater than 100 Gbit/s, over distances approaching 500 km have been demonstrated.

Demultiplexing of OTDM Signal at Receiver

For OTDM communication systems with data rates above 40 Gbit/s, it is not feasible to use electrical switching. Indeed for ultrahigh-speed systems operating at 100 Gbit/s and beyond, the only solution for demultiplexing is to use all-optical switching in which optical control signals are used to switch the OTDM data signal. All-optical switches normally use nonlinear optical effects either in optical fiber or semiconductors. A typical scenario (as presented in Fig. 5) involves the injection of both the OTDM data signal and an optical control signal into the nonlinear device. The control signal consists of high-power ultrashort pulses at the repetition rate of the individual channels within the temporally multiplexed signal, and by synchronizing it with one of the OTDM channels it is possible to demultiplex this channel from the high-speed OTDM signal.

Two of the most popular all-optical demultiplexers are the nonlinear optical loop mirror (NOLM), and the terahertz optical asymmetric demultiplexer (TOAD). The NOLM is based on the nonlinear refractive index of optical fiber. It essentially consists of a 2×2 fiber coupler with its two outputs joined using a certain length of fiber. When an OTDM signal is injected into an input port of the coupler, it splits into two counterpropagating components in the fiber loop, and when these components recombine and

Fig. 5 Configuration of OTDM demultiplexers using (a) an interferometer based on nonlinear phase shift in fiber or semiconductor optical amplifiers, and (b) four-wave mixing in fiber or semiconductor optical amplifiers.

interfere at the coupler, the overall signal is output through its initial input port. If we now inject a high-power control signal directly into the loop, such that it propagates unidirectionally, and is synchronized with one of the OTDM data channels, then the phase shift induced by the control on the copropagating signal channel (via the nonlinear refractive index of the fiber) results in that particular channel being switched out to the second input port of the coupler. The remaining data channels of the OTDM signal are once again output through the same port that they entered the coupler. As this particular nonlinear effect in fiber (known as the Kerr effect) has a femtosecond response time, it should be possible to realize extremely high-speed switching with the NOLM. Demultiplexing at data rates in excess of 100 Gbit/s has already been achieved using this technique. One disadvantage of this method is that the nonlinear index coefficient of standard fiber is very small, so in order to achieve the required phase shift from the control pulse, it is necessary to use a fiber loop of around 1 km in length (depending on the power of the control pulse used). This length may affect the overall stability of the demultiplexer and its ability to be readily integrated into high-speed OTDM systems. However, it should be noted that recent developments in the design of high-nonlinearity fibers may reduce this problem.

The second all-optical switch mentioned above is known as a TOAD. Whereas the NOLM is based on the nonlinear refractive index of the fiber, the TOAD is based on a nonlinear optical effect in semiconductor optical amplifiers (SOA). The overall setup for a TOAD is very similar to that for a NOLM, except that a semiconductor amplifier, as shown in Fig. 5, replaces the length of fiber in the loop. As for the NOLM, the OTDM data signal is injected into the TOAD using one input of the coupler, such that it splits into two counterpropagating signals, while the control signal propagates unidirectionally in the loop containing the SOA. By synchronizing the control with one channel in the OTDM signal, this particular channel is switched out. Although the response time of a TOAD-based switch may not be as fast as the NOLM, it does have the major advantage that it can be developed into a very compact demultiplexer, suitable for deployment in OTDM-based communication systems.

In addition to the NOLM and the TOAD structures, which are both interferometric-based switches, it is also possible to use four-wavemixing (FWM) in optical fiber or semiconductor optical amplifiers to carry out the demultiplexing of OTDM signals. In this case, the high-power control pulse is synchronized with one of the OTDM channels such that the wavelength of this channel is shifted as it passes through the nonlinear device. Optical filtering may then be used to select out the demultiplexed channel.

As we discussed in the section on demultiplexing, whatever specific all-optical switching technique is employed, we need to generate an optical clock signal for use as the control pulses. This implies that it is necessary to extract a clock at the base rate of the individual data channels from the high-speed OTDM signal. Depending on the base data rate, which may be anywhere from 2.5 to 40 Gbit/s for typical OTDM systems, different clock recovery techniques have been demonstrated. These range from basic electronic clock recovery schemes to more advanced techniques based on self-pulsating laser diodes and optical phase-locked loops.

OTDM Networking Issues

The previous section has predominantly dealt with the basic elements required to implement a high-speed OTDM transmission link. However, if we are to use OTDM technology for high-speed networking, then additional elements will be required. One of

Fig. 6 Schematic representation of a ring network employing OTDM with a separate fiber for clock distribution.

Fig. 7 Configuration of an add/drop multiplexing node for use in OTDM-based communication systems.

the most important of these is an add/drop multiplexer (ADM). The ADM allows us to switch out one channel from the OTDM signal, and then insert another data channel for transmission in the vacant bit slot. If we consider employing OTDM in a ring configuration network, then a typical architecture for the network will be as shown in Fig. 6. The high-speed OTDM data signal propagates around the closed fiber loop, and each node in the network is responsible for switching out the data it requires, in addition to inserting the data it wishes to transmit onto the fiber ring. Add/drop multiplexing is thus imperative in developing such an OTDM ring network.

The configuration for each node in an OTDM ring network is shown in Fig. 7. At each node it is initially necessary to recover the base rate clock signal. The recovered clock is then used in conjunction with the OTDM signal to switch out the required data channel from the multiplexed signal. When an add/drop multiplexer is used for this purpose we obtain two outputs, one being the demultiplexed data, and the other being the OTDM signal less the switched-out data channel. A simple fiber coupler can subsequently be used to allow this particular node to insert the data it wishes to send into the free bit slot of the overall OTDM signal. This obviously requires control of the relative delay between the OTDM signal and the local data channel to be inserted onto the fiber ring, to ensure that the local data are inserted into the vacant bit slot. A number of techniques have been used for implementing add/drop multiplexers in OTDM-based networks. These have used either fiber interferometers, or interferometers using semiconductor optical amplifiers, in which we obtain both the demultiplexed data signal and the OTDM signal less the switched-out channel (to which the local data channel is then added). The continuing development and enhancement of ADM devices for OTDM systems will be vital for the future implementation of OTDM communication systems.

Table 2 Main elements of an OTDM communications system

<i>Device</i>	<i>Principal function</i>	<i>Technical implementation</i>
Optical pulse source	Generate ultrashort optical pulses suitable for transmission in high-speed OTDM systems	Gain-switching, mode-locking, or external modulation techniques
Multiplexer	Multiplex individual pulse data channels in the temporal domain using appropriate delays to achieve an OTDM signal	Passive couplers with fixed fiber delay lines, or planar waveguide circuits (for accurate control of delays)
Optical amplifier	Amplify the OTDM signal during fiber transmission to overcome fiber loss	Fiber doped with rare earth materials (e.g. erbium) in conjunction with pump laser
Transmission fiber	Transmit the OTDM data signal from transmission site to required receiver	Standard single-mode fiber, dispersion shifted fiber, or other specialty fiber may be used
Clock recovery	Extract clock (at base rate of individual channels) from OTDM data signal at receiver, for use in demultiplexing	Electronic or optical phase-locked loops, self-pulsating lasers, or mode-locked ring laser techniques
Demultiplexer	Demultiplex one of the channels from the overall OTDM signal	Interferometric or four-wave mixing techniques based on fiber or semiconductor nonlinearity
Add/drop demultiplexer	Extract one channel from OTDM data signal, and insert a local channel into the empty time slot for transmission	Similar technical implementations to demultiplexer described above

Conclusion

In this article we have explained the main ideas involved in building OTDM communication systems, and also introduced the principal technologies which are required to do so. OTDM is an extremely wavelength-efficient technique for delivering high-capacity data signals, and it may be used both for long-haul transmission and networking around metropolitan areas. In addition, unlike WDM, it does not require a different wavelength source for each channel in the multiplexed signal. Despite these and other advantages, OTDM is still way behind WDM when it comes to commercial maturity, with no OTDM systems currently available in the telecommunications market. However, the technologies required to implement high-speed OTDM systems (outlined in [Table 2](#)), including ultrashort pulse sources, clock extraction circuitry, and demultiplexing devices, are developing rapidly. It therefore seems likely that in the future, OTDM technology may be used for enhancing the overall capacity of optical communication systems.

One possibility for employing OTDM systems would be for upgrading installed WDM networks. The current method for improving WDM networks involves using more wavelength channels, but it may also be feasible to increase the overall capacity by developing hybrid WDM/OTDM communications systems. In such a system, each wavelength channel may carry aggregate data rates in excess of 100 Gbit/s, achieved using OTDM. The design of these hybrid networks would permit switching of the optical data signals to be carried out at two different levels in the overall network. The WDM signals could be switched coarsely using passive filtering devices, and the OTDM data channels could be switched with fine granularity using one of the all-optical switching techniques available.

Introduction

Optical fiber telecommunications has changed human society forever, providing the capacity for affordable and ubiquitous communication. It provides data rates and transport economies far in excess of those available using purely electronic means. It is doubtful whether the Internet and worldwide web, or the vast infrastructure of wireless cellular telephony, would be viable without optical fiber technology. Its rapid development and acceptance has been driven largely by contemporaneous successes in manufacturable low-loss optical fiber cables, sensitive pin-FET photoreceivers, and reliable high-performance laser diode-based transmitters. The earliest developments in silica glass fibers at Standard Telecommunication Laboratories, UK, (then part of the US-based ITT Corporation) and Corning Glass Works (USA) in the 1960s and 1970s, were pivotal in determining the directions of modern fiber technology, as were later key inventions of rare-earth doped fiber amplifiers at the University of Southampton (UK) and AT&T Bell Laboratories (USA) in the 1980s and early 1990s. However, perhaps the greatest contributors to the success of fiber optics have been semiconductor injection lasers, or laser diodes, which in various forms have made up the vast majority of all fiber optic transmitters, and the entirety of long-haul transmitters, as well as pump sources for the doped-fiber amplifiers which enable modern networks. The fascinating story of the development of fiber optics is to a large extent driven by the dramatic progress in the development of high-performance, reliable semiconductor lasers. These emitted at wavelengths near 1300 and 1550 nm, which respectively correspond to the dispersion and attenuation minima of single-mode silica optical fibers.

Semiconductor Laser Principles

Semiconductor lasers were first demonstrated in research laboratories at General Electric, IBM Corporation and the MIT Lincoln Laboratory (all USA) as early as 1962, although it took almost two decades for the basic science and engineering of materials, fabrication, reliability, and performance design issues to be developed sufficiently for their use in practical communication systems. Early successes were obtained using the GaAs/AlGaAs lattice-matched material system, in which a lightly doped GaAs or ternary compound AlGaAs active layer is sandwiched between two lattice-matched heterojunctions with n- and p-doped AlGaAs layers with higher Al fractions than the active layer, so that their refractive indices are lower and their bandgaps higher, providing optical and charge-carrier confinement. In all cases the material is epitaxially grown, meaning that the entire laser chip forms a single crystal. The gain, and hence the laser emission, occurs at the direct bandgap of the active layer, at wavelengths in the range 750–870 nm depending on the Al fraction. Later evolutions used the quaternary compound GaInAsP clad by InP guiding layers, where the In and P fractions are chosen to match the lattice constant to the InP substrate.

In general, optical gain in a laser diode is generated by creating an electron-hole plasma in the vicinity of the forward-biased junction, a situation corresponding to population inversion in a conventional laser, and with sufficient forward current the material becomes transparent, in that the gain exactly equals the absorption and scattering losses, at a particular wavelength. When this arrangement is enclosed within a suitable optical cavity, and the forward current is increased further, the system begins to lase, that is to oscillate continuously to produce coherent optical radiation at a wavelength which satisfies two basic conditions: it must be within the set of wavelengths at which the material produces sufficient gain, and it must be close to one of the electromagnetic modes at which the optical cavity is resonant. These conditions, which define lasing threshold, are characterized by the equality of the optical gain and the total losses, that is the material losses (absorption, scattering, and free-carrier plasma) and the cavity losses which include the light output.

Early laser diodes in both the GaAs/AlGaAs and GaInAsP/InP systems were of the edge-emitting type, in which the light is emitted from the edge of the laser chip, perpendicular to the growth direction in the plane of the wafer. Although this geometry complicates laser production flow, particularly the testing function which requires that the wafer be scribed into bars to define the laser output facets, edge-emitting lasers (EELs) make up the vast majority of optical fiber transmission sources. An alternative laser diode structure is the vertical cavity surface-emitting laser (VCSEL), in which emission occurs in the growth direction perpendicular to the plane of the wafer. VCSELs offer major advantages in spectral stability, beam quality, manufacturability and cost, but their output powers are low (a few mW) and they are not yet available at the key telecommunication windows around 1300 nm and 1550 nm, due to difficulty in forming the necessary high-reflectivity Bragg mirrors in the GaInAsP/InP material system. Major initiatives are currently underway to produce long-wave VCSELs in the GaAs/AlGaAs system using InAs quantum dots, or dilute nitrides such as InGaAsN, or hybrid approaches such as InP-based gain media fused to high-reflectivity mirrors using GaAs/AlGaAs, dielectric coatings, air gaps, and others. At present, however, all long-haul optical fiber transmission is based on edge-emitting laser diodes fabricated in GaInAsP/InP.

General Structure and Requirements of Optical Fiber Communication Systems

The first optical fiber communication links were simple point-to-point affairs, consisting essentially of series-connected transmitters, fibers, and receivers. The transmitters were simple Fabry–Perot laser diodes, onto which data were encoded by direct digital modulation of the injection current at rates ~ 100 Mbit/s. The first commercial optical fiber link was built in 1976, a single fiber cable linking two switching centers of the Illinois Bell Telephone Co just 2.5 km apart in the Chicago metropolitan area, using 850 nm GaAs laser technology. In 1988, the first transatlantic fiber link, AT&T's TAT-8, was completed linking endpoints in New Jersey, England, and France with three fiber pairs carrying signals generated by 1300 nm GaInAsp single mode lasers. In these early systems, data were regenerated frequently by repeaters each consisting of a receiver, signal conditioner and transmitter. Each fiber in TAT-8 carried a single optical frequency modulated at 280 Mbit/s and the construction cost of the system was $\sim \$50$ k/km, resulting in an economic figure of merit of over $\$600$ k/Mbit/s. Twenty-five years later, current systems cost the same per kilometer to build in absolute dollars despite inflation, a major effective cost reduction enabled largely by replacement of the expensive repeaters by doped-fiber optical amplifiers. Moreover, each fiber is now highly multiplexed, with the potential for hundreds of wavelengths each carrying 10 Gbit/s signals generated by 1550 nm laser transmitters, so that the unit cost has plummeted to $\sim \$200$ /Mbit/s, a reduction of three and a half orders of magnitude.

In the remainder of this article, we will describe transmitters for both short- and long-haul systems where the channel spacing is only tens of GHz in the optical carrier frequency. Modern short-haul systems either feed client networks as part of bi-directional transceivers, or drive metro and local access networks connected directly by photonic switches to terminals of the long-haul systems.

DWDM Transceivers

Modern practice uses modular units containing transmitters and receivers allowing bi-directional data flow. In the send mode, data are applied to a long-haul transmitter at the local (client) source and coupled through the external fiber network to the remote long-haul receiver. In the receive mode, data arrive from a remote long-haul transmitter and are coupled (via a regenerator including signal conditioning, clock recovery, and error correcting steps) to a local short-haul transmitter leading to the client's internal network. Each transceiver card therefore contains a long-haul transmitter and receiver set (known collectively as dense wavelength division multiplexing (DWDM) transport devices) and a short-haul transmitter and receiver set (known as client interfaces or local transport devices).

Transmitter Requirements

Short-haul transmitters may be simple Fabry–Perot edge-emitting laser diodes, or vertical cavity laser diodes, or even superluminescent LEDs for sub-Gbit/s data rates. They are generally not required to be at one of the minimum-loss telecom windows near 1550 nm, as the transmission distances are short. However, as client networks grow into large metropolitan networks, it is likely that 1300 nm sources will be used to minimize dispersion. Power requirements are modest, a few mW peak, at data rates ~ 1 –10 Gbit/s. Single mode laser emission and polarization control are not required by present day systems, although polarization-mode dispersion may limit transmission at higher data rates. Both return-to-zero (RZ) and nonreturn-to-zero (NRZ) coding may be used, and direct modulation of the laser amplitude is the norm.

For long-haul transmitters the situation is dramatically different. Operation in one of the standard erbium-doped fiber amplifier (EDFA) bands near 1550 nm is mandatory: the C (conventional) band extends from 1530–1565 nm, the S (short-wave) band from 1460–1530 nm) and the L (long-wave) band from 1565–1625 nm. In the C-band, output powers ~ 10 mW are generally sufficient, and powers above ~ 30 mW are limited by nonlinear effects such as self-phase modulation and four-wave mixing in the fiber. In the S- and L-bands, where the available gain from EDFAs is less, lasers may need to operate close to the nonlinear limit, several tens of mW, although various schemes (differential pumping, gain-flattening filters, etc.) are being evaluated to flatten the global EDFA gain spectrum.

In current practice, a single fiber utilizing DWDM, using only the C-band, can carry up to 1 Tbit/s comprising 100 channels at 10 Gbit/s on each channel, the current standard. For such performance a channel spacing of 50 GHz in optical frequency is required. Using all three bands with similar density would enable ~ 3 Tbit/s, which could be doubled by using 25 GHz channel spacings. Ultimately, even higher channel densities and hence overall system data rates are possible, with a practical limit ~ 10 Tbit/s. The channel spacing is a key parameter in that it determines the laser design, specifically its spectral stability and linewidth, and the overall transmitter design in that laser chirp (modulation induced dynamic spectral shift) must be less than half the channel spacing. In practice, only single-wavelength and coarse wavelength division multiplexing (CWDM) systems may be modulated directly. All modern DWDM systems require external modulation, for example using electro-absorption or Mach–Zehnder interferometric devices outside the laser cavity. For the latter cases, stabilization of the laser wavelength is required for example by on-chip gratings to form distributed feedback (DFB) or distributed Bragg reflector (DBR) lasers, or by external fiber gratings.

Directly Modulated Lasers

Direct modulation of semiconductor lasers is convenient and effective: by modulating the laser injection current, one modulates the carrier density and hence the optical gain, resulting in modulation of the laser output up to ~ 10 Gbit/s. The actual modulation bandwidth is determined by interactions between photons and carriers, whose respective decay lifetimes, τ_s and τ_p , are determined by cavity losses and total recombination rates. The simplest form of such interactions is described by the photon and carrier rate equations for the injected carrier density N and photon density S in a single lasing mode:

$$dN/dt = J/ed - gNS - N/\tau_s \quad (1)$$

$$dP/dt = gNS + \beta N/\tau_s - S/\tau_p \quad (2)$$

where J is the injected current density, e the electronic charge, d is the thickness of the active region (hence J/ed is the rate of injection of carriers per unit volume), g is the gain coefficient per unit length and β is the fraction of the spontaneous emission coupled into the lasing mode, typically $\sim 10^{-2}$ – 10^{-5} for edge-emitting lasers (product of geometric and spectral overlap factors). These equations simply state that the rate of change of the carriers or photons is given by the rate of generation less the loss rate. Additional terms are required in the presence of optical feedback or coupling (in which case the photon density is replaced by the complex amplitude and phase of the optical electric field) or for extremely rapid modulation where the traveling wave nature of the disturbances in the photon fields is significant. These so-called traveling-wave rate equations for the photons are of the form:

$$dS_+/dt + cdS_+/dz = gNS_+ + \beta N/\tau_s \quad (3)$$

$$dS_-/dt - cdS_-/dz = gNS_- + \beta N/\tau_s \quad (4)$$

with the same carrier rate equation as [1] using the total photon number S made up of the forward-traveling component S_+ and the backward-traveling component S_- : $S = S_+ + S_-$.

Both sets of rate equations are based on approximations such as homogeneous gain broadening, neglect of transverse field effects, and diffusion. These are valid in most situations but care is required when analyzing lasers with large transverse apertures, or when ultrashort (picosecond) pulses are involved.

Small-Signal Modulation

Small-signal modulation may be analyzed by a linear perturbation analysis of the rate equations, leading to a conjugate pair of poles in the response function, with damped relaxation oscillations at frequency:

$$f_R = (1/2\pi)\sqrt{(gS_0/\tau_p)} \quad (5)$$

or, in terms of the injected current density J (assuming $S \sim G(J - J_{th})/ed$ with Γ the electromagnetic confinement factor of the mode):

$$f_R = (1/2\pi)\sqrt{[\Gamma g(J - J_{th})/ed]}$$

f_R can be regarded as the resonant frequency for the interaction between the carriers and photons. As a practical matter, lasers can be modulated up to $\sim 2f_R$ but the modulation response rolls off rapidly with increasing frequency above f_R . Using explicit expressions for the threshold gain, we can write f_R as:

$$f_R = (1/2\pi)\sqrt{[(GN_T g\tau_p + 1)(J/J_{th} - 1)/\tau_s\tau_p]} \quad (6)$$

where N_T is the transparency carrier density $\sim 10^{18} \text{ cm}^{-3}$. f_R can take values in excess of 10 GHz for a well-designed laser. It should be noted, however, that high modulation bandwidth almost always requires high differential gain dg/dN and short τ_p . Increasing dg/dN requires p-doping (which increases optical loss) and/or some special quantum-confining structure such as wells, wires, or dots. Decreasing τ_p inevitably leads to greater optical loss and thus a higher threshold.

The damping rate of the relaxation oscillations is also important in limiting modulation bandwidth, and also (when increased) in reducing the sensitivity of the laser to optical feedback. For bulk or quantum well lasers, the condition for critical damping is $A^2 = 4B$ with $A = (S/g\tau_s - \sigma[N - N_T])/g\tau_p$ and $B = \sigma[1 + (S_0/g\tau_s) - (1 - \beta)(N - N_T)]$. For quantum dot lasers there are additional damping terms due to carrier transport and thermalization which may restrict small-signal modulation bandwidths to a few GHz.

Experimentally, small-signal modulation properties may be determined using a simple sampling oscilloscope, low-noise tunable signal generator and spectrum analyzer. A combination of these elements with automated frequency sweeping may be found in a scalar network analyzer acting as an s -parameter test set. The modulated laser is connected to port 1 and a high speed photodetector connected to port 2, then a swept-frequency measurement of the transfer characteristic s_{21} is performed. In addition to the limitations on modulation response due to the carrier-photon resonance, practical lasers are limited by RC parasitics in the laser chip (junction impedance) and its package. For the highest modulation speeds, packages need to be designed as microwave transmission line components with effective impedance matching and low back reflections, as characterized by the voltage standing wave ratio (VSWR).

Large-Signal Modulation

Large-signal direct modulation can be analyzed by numerical integration of the rate equations. In general, its results are beyond the scope of this review, but for effective high-speed response, digital modulation of laser diodes should be carried out with a pre-bias close to threshold. Modulation bandwidth also increases with laser power, which is limited for systems considerations by fiber nonlinearities, and for reasons of laser reliability. In pulse code modulation, care must be taken that the laser is near critical damping, to minimize thermal patterning effects due to long strings of ones (high power) or zeros (low power). Experimentally, large signal modulation is analyzed by constructing eye diagrams, in which pulse traces on a fast oscilloscope are continuously overlaid when the laser is modulated using pseudorandom binary pulses. When the signal quality is high, the high and low digital levels are easily distinguishable, resulting in an open 'eye' in the accumulated traces.

Requirements for Externally Modulated Lasers

The requirement for external modulation occurs when the laser chirp exceeds half the desired channel spacing in the communication system. Chirp occurs due to changes in the refractive index, and hence the optical phase, during modulation. This dynamic phase shift then results in an instantaneous frequency shift. For direct modulation we have instantaneous wavelength

$$\lambda(t) = \lambda(0)\mu(t)/\mu(0) \quad (7)$$

Where $\mu(t)$ is the refractive index at time t . μ shifts with carrier density N due to combinations of several factors (free carrier plasma dispersion, thermal bandgap shrinkage, bandgap renormalization, dynamic Burstein–Moss effects) which give $d\mu/dN \sim -3 \times 10^{-20} \text{ cm}^3$, which for large signal digital modulation can result in tens of GHz. The actual degree of chirp depends on the so-called antiguiding or linewidth enhancement factor α given by

$$\alpha = -2k_0(d\mu/dN)/(dg/dN) \quad (8)$$

where $k_0 = 2\pi/\lambda_0$ is the free-space wavenumber. α as defined is positive, typically in the range 2–7 depending on the material, operating carrier density, and wavelength relative to the gain peak. Distributed feedback (DFB) or distributed Bragg reflector (DBR) lasers, which use integrated gratings to control the lasing wavelength, can have lower chirp by detuning from the gain peak but therefore are likely to require careful temperature stabilization. Quantum dot lasers, based on 3D nanoclustered active regions, have the potential for very low chirp, narrow linewidths, and reduced wavelength shifts, so that directly modulated DWDM transmitters may be possible.

Integration of laser diodes with electro-absorption or Mach–Zehnder type modulators is achieved in the transmitter optical subassembly and may in some cases be accomplished by monolithic integration on the same chip. Using separate modulators allows each device to be optimized independently but requires optical assembly, alignment, and retention. Mach–Zehnder modulators in X-cut lithium niobate, for example, have essentially zero chirp and can operate to 40 Gbit/s and above, with dynamic extinction ratios (ratio between fully on and fully off) of ~ 20 dB. Integrated semiconductor M-Z modulators have chirp an order of magnitude less than those of directly modulated lasers, so that channel spacings ~ 25 GHz are possible in DWDM systems with suitable temperature and wavelength controls. Although the details of such modulators are beyond the scope of this article, the laser requirements are to generate ~ 10 mW of continuous power with stable center wavelength and narrow linewidth. Such lasers are usually mounted in hermetic packages (e.g., the current 14-pin butterfly standard) with integrated thermo-electric cooler, power monitor photodiode, an optical isolator to suppress optical backreflections which cause instabilities and self-pulsing, and optional wavelength locking optics.

Reliability of Lasers in Fiber Optic Systems

From the early days, when laser diode lifetimes were measured in seconds even at cryogenic temperature, enormous progress has been made in achieving materials purity and reducing crystalline defects. Today's fiber optic laser transmitters have projected lifetimes of decades. In common with electronic devices, diode lasers fail at a rate given by a 'bathtub' curve, that is the failure rate $r(t)$ defined as the probability of failure per unit time at time t , has relatively high values at low t (early failures) and high t (wearout failures) and very low values in between. In terms of the population of lasers $n(t)$ we have:

$$r(t) = (-1/n(t))dn(t)/dt \quad (9)$$

If Δn is the number of samples which fail in time Δt , then assuming Δt begins at $t=0$, the effective or average failure rate r_{eff} over the interval is

$$r_{\text{eff}}(t) = \Delta t \Delta n / n(0) \quad (10)$$

In reliability science it is customary to define r_{eff} in FITs (failures integrated in time) with the time-span chosen to yield statistically significant numbers. For electronic and photonic devices, it is customary to select the time interval $\Delta t = 10^9 \text{ h}$ (1 billion operating hours), so that if 1% of the devices fail in 10 years ($\sim 10^5$ hours) we have $r_{\text{eff}} \sim 100$ FITs, which is the order of magnitude required by modern fiber optic laser sources.

In terms of actual statistical models, failure rates can be estimated using failure probability density functions $f(t)$. This is related to $r(t)$ by $f(t) = r(t)S(t)$ where $S(t)$ is the cumulative probability of surviving until t . When $r(t)$ is nearly constant, as in early failures due to material defects or process errors, the statistics are approximately exponential:

$$f(t) + (1/\tau)\exp(-t/\tau) \quad (11)$$

or Weibull-distributed (an exponential is a Weibull distribution with $\beta=1$):

$$f(t) = (\beta/t^\beta)t^{\beta-1}\exp\left[-(t/\tau)^\beta\right] \quad (12)$$

but this description is not suited to wearout failures for which $f(t)$ shows a significant increase as the population ages. For such cases, the lognormal distribution is often applicable:

$$f(t) = (1/\sigma t \sqrt{2\pi})\exp[-(\ln t - \ln \tau)^2/2\sigma^2] \quad (13)$$

where in each case τ is approximately the mean time to failure (MTTF).

Laser diodes undergo standardized qualification tests to demonstrate sufficient reliability prior to being used in commercial systems. Operationally, failure statistics must be tabulated and the best fit obtained. Burn-in procedures are used to screen early failures. Chip and module failures should be distinguished clearly, as the latter includes many additional factors such as thermal and power management, light coupling, mechanical or chemical integrity.

Given that effective lifetimes of decades are required, it is clearly necessary to accelerate aging to produce statistically meaningful failure rates in reasonable times $\sim 10^3$ h. For the most common modes of laser chip degradation, due to recombination-induced aggregation of defects in the crystalline epitaxial material, these are thermally activated and current driven, so that it is customary to use a modified Arrhenius law at temperature T :

$$\tau \sim (1/J^n)\exp(E_a/k_B T) \quad (14)$$

where J is the operating current density, n is an index ~ 2 , E_a is the activation energy, and k_B is Boltzmann's constant. In terms of thermal acceleration, we have a factor $F = \tau(T_A)/\tau(T_B)$ with:

$$F = \exp[(E_a/k_B)(1/T_A - 1/T_B)] \quad (15)$$

Typical values of E_a for laser diodes are ~ 1 eV so that acceleration factors $\sim 10^3$ are possible.

Finally, it should be noted that laser diodes are generally subject to catastrophic failure in the event of overdriving or static discharge, the failure mode being thermal facet damage at ~ 1 – 10 MW/cm² for continuous-wave operation, the exact value depending on the material, surface preparation and specifically surface state absorption and its temperature coefficient.

Conclusions

Laser diodes are ideal sources for optical fiber communication systems and have propelled the development of fiber optics from its origins in the 1960s to the present day. They are compact, rugged, efficient, and reliable sources of light at key wavelength ranges such as 1300–1310 nm (short haul high speed links) and 1500–1600 nm (long haul amplified systems). They are capable of direct modulation at gigabit rates for simple systems but require external modulation and careful wavelength control for dense wavelength division multiplexed terabit systems. Transmitter lasers for real systems must satisfy stringent reliability conditions.

Broadband Passive Optical Access Networks

Elaine Wong and Maluge P Imali Dias, The University of Melbourne, Parkville, VIC, Australia

Introduction

The exponential growth in Internet and mobile traffic along with bandwidth-intensive applications, has continued to drive the deployment of fiber networks deeper into the access network segment (Wong, 2012). In future-proofing against the forecasted increase in bandwidth demands, Fiber-To-The-X (X=home, curb, building) networks have been deployed in various parts of the world. Offering direct fiber connection to or close to the home, FTTx deployments can assume point-to-multipoint (PtMP) or point-to-point (PtP) physical topologies, as illustrated in Fig. 1 (Wong, 2012). Driven by low cost and low energy consumption per bit, most deployed FTTx models are based on the passive optical network (PON) topology (Wong, 2012). Typically, a PON has a PtMP topology and comprises a central office (CO) which houses multiple optical line terminals (OLTs), optical network units (ONUs) residing in subscriber premises, and a passive splitting optical distribution network (ODN) consisting of a feeder fiber, passive optical splitter(s), and multiple distribution fibers.

Commercial PONs such as Broadband PON (BPON) (ITU-T, 2005), Gigabit PON (GPON) (ITU-T, 2008a) and Gigabit Ethernet PON (GE-PON) (IEEE, 2004) are deployed around the world. GPON systems are specified by the ITU-T G.984 Gigabit PON (GPON) standard (ITU-T, 2008a) whereas GE-PON is specified by the IEEE 802.3ah Gigabit Ethernet PON (GE-PON) standard (IEEE, 2004). Both GPON and GE-PON are classified as time division multiplexed/time division multiple access (TDM/TDMA) PONs. In TDM/TDMA PONs, encrypted information is broadcast to all ONUs in timeslots at a line-rate of 2.5 Gb/s for GPON and 1.25 Gb/s for GE-PON in the downstream direction. Due to the power-splitting ODN, all time slots are received by each ONU but only particular time slots addressed to the ONU through its media access control (MAC) destination address, are detected and received. In the upstream direction, burst mode TDMA is used between ONUs to share the aggregate 1.25 Gb/s upstream bandwidth (for both GPON and GE-PON). If required, a dedicated radio frequency (RF) channel can be added to broadcast TV/video data (Wong, 2012).

One major disadvantage of the power-splitting nature PONs is the limitation in further scaling of bandwidth, reach, and subscriber count. Specifically, the splitting loss of the ODN is a strong function of the number of supported subscribers thereby constraining any possible increase in user count, reach, and/or average user data rate. To overcome this limitation and to support future business, residential, back- and front-hauling bandwidth needs, next-generation PONs commonly referred to as NG-PON1, with a maximum line rate of 10 Gb/s, were recently standardized. Defined by both IEEE (2009) and ITU-T (2010), these standards allowed for backward compatibility and co-existence with the current-generation GPONs and GE-PONs, thus enabling progressive upgrades with minimal capital investment on the external plant and operational impact on existing users.

The PtP network can overcome the limitation in bandwidth, reach, and subscriber count of power-splitting PONs. In a PtP network, dedicated fiber and hence bandwidth is assigned between the CO and each ONU. Other beneficial features include enhanced data privacy and security. Nonetheless, PtP suffers from high fiber count and terminations at the CO (one per ONU) and thus requires high density fiber management. While the focus of this article is on PONs that adopt the PtMP topology, PtP Ethernet

Fig. 1 Schematic of network structure showing the physical topology options of access networks. Reproduced from Wong, E., 2012. Next-generation broadband access networks and technologies. *IEEE/OSA J. Lightw. Technol.* 30(4), 597–608.

is popular in some parts of the world, e.g., Japan, China and Sweden, and has been deployed to connect high revenue fixed access and mobile business customers that require guaranteed bandwidths (Förster, 2006).

New access technologies beyond NG-PON 1, namely 10 Gb/s TDM/TDMA systems, are being explored to support symmetrical average data rates of ~ 1 Gb/s per user, an extended system reach of 60–100 km, a high subscriber count of up to 1000, and heterogeneous service convergence, while meeting the cost constraints of the access market. The standardization of time and wavelength division multiplexed PON (TWDM-PON) as the selected NG-PON2 technology, specifies a 40-Gb/s downstream capacity using an underlying hybrid time and wavelength division multiplexing scheme (ITU, 2013). Each wavelength in a TWDM-PON is shared between multiple ONUs by employing time division multiplexing and multiple access mechanisms.

Beyond the promises of NG-PON2, wavelength division multiplexed (WDM) PONs are being explored as the next-generation solution. The idea of exploiting wavelength division multiplexing in access networks was conceived in the late 1980s (Oakley, 1988) but significant advancement of key enabling technologies such as the athermal arrayed waveguide grating (AWG), WDM filter, reflective semiconductor optical amplifier (RSOA) and Fabry-Perot laser diode (FP-LD) has fuelled the resurgence of WDM-PON research in the last 10 years. A number of commercialized WDM-PON systems have been deployed to service customized business and wireless/wireline backhaul markets, e.g., (see Section Relevant Websites). In a WDM-PON, each end user is given dedicated capacity through the assignment of unique upstream and downstream wavelength channels. Concurrently, extended-reach PONs (ER-PONs) are being explored to consolidate metropolitan area and access networks (Davey *et al.*, 2009). Serving an increased number of clients, accommodating high bandwidth applications, and an increased network span, ER-PON deployments promise lower capital expenditure (CAPEX) and operational expenditure (OPEX) due to reduced number of active network interfaces and elements in the field. More recently, the use of orthogonal frequency division multiplexing (OFDM) in combination with WDM has been vigorously explored for application in the access segment (Cvijetic, 2012). In an OFDM-PON, data is carried by multiple orthogonal subcarriers, and a flexible 3D bandwidth allocation can be realized in time, frequency and modulation formats domain.

This review article is organized as follows. In Section Time-Division Multiplexed (TDM) Passive Optical Networks, we will introduce the early standardized TDM-PONs including BPONs, GPONs and GE-PONs. Then, the standardized 10G-PONs including ITU-T NG-PON1 and IEEE 10 G-EPON will be introduced in Section NG-PON1. In Section NG-PON2, the TWDM-PON structure based NG-PON2 will be introduced from the viewpoint of both physical layer and protocol layer. High capacity TWDM-PONs with advanced techniques to enable 100 Gb/s or beyond capacity will also be discussed. In Section Future PONs, future PONs with potential standardization possibility including WDM-PONs, extended-reach PONs and OFDM-PONs will be discussed. Finally, we will conclude this article in Section Summary and Conclusion.

Time-Division Multiplexed Passive Optical Networks

BPONs

The Broadband Passive Optical Network (BPON) was firstly developed by the Full Service Access Network (FSAN) working group in 1995 and was standardized by the International Telecommunications Union (ITU) in 2001 (ITU-T, 2008a). BPON is based on the asynchronous transfer mode (ATM) protocol and has a maximal downstream rate of 1244.16-Mbit/s and upstream rate of 622.08-Mbit/s. As discussed in Section Introduction, downstream signal is broadcast to all ONUs on the PON. To avoid collisions in the upstream direction, upstream transmission time slots from each ONU are controlled and granted by the OLT in the CO through Time Division Multiple Access (TDMA) (ITU-T, 2008a). The line code employed by BPON in both downstream and upstream transmissions is the Non-Return Zero (NRZ) modulation format. The typical operating wavelength for downstream and upstream is 1550 nm and 1310 nm, respectively.

The BPON MAC frame consists of different numbers of fixed size ATM cells, the actual number depending on the rate of transmission, as shown in Fig. 2. For the downstream MAC frame, a Physical Layer Operation, Administration, and Maintenance (PLOAM) is inserted at the beginning of every 28 ATM cells. PLOAMs are also used to carry grant information relating to an ONU's upstream access. Through PLOAM, an OLT in the CO can allocate and divide the upstream access bandwidth amongst different ONUs. Downstream transmission from the OLT is broadcast to every connected ONU. Each ONU will selectively detect its own cell according to the bandwidth allocation scheduled in OLT. In the upstream direction, transmission occurs in ATM cells with 3 overhead bytes per cell in its own time slot. Each ONU can only transmit its ATM cells during pre-determined time slots. Due to ONUs not being equidistance to the OLT, the OLT will receive burst-mode signals at differing power levels, each from a different ONU.

Though being the first-standardized PON, the uptake of BPON was slow and is currently rarely deployed due to the high cost per unit bandwidth. Further, the use of ATM cells within this MAC frame results in complex processing and large overhead (a 5-byte header to each 48-byte payload), thus limiting large-scale deployment.

Gigabit PONs

The Gigabit PON (GPON) was first standardised by the FSAN/ITU-T under ITU-T G.984 listing different aspects of the GPON such as general characteristics, physical medium, and management and control (ITU-T, 2008a). The standardized GPON supports data

Fig. 2 Frame structure of BPON for 1244.16/622.08-Mbit/s. Adapted from ITU-T, 2008a. G.984 – Series recommendation, Gigabit-capable passive optical networks (G-PON).

rates of 2.5 Gb/s and 1.25 Gb/s in the downstream and upstream directions, respectively. Today, GPON is one of the most popular technology of choice in some areas of Europe and North America.

Before entering the physical medium, Ethernet frames are encapsulated into GPON Transmission Control (GTC) layer encapsulation method (GEM) frames. GEM frames are, in turn, encapsulated into GPON Transmission Convergence (GTC) frame (in both upstream and downstream directions) (CommScope, 2013). Fig. 3 illustrates a downstream GTC frame in detail (CommScope, 2013). In GPON, the GTC layer is responsible for aggregating traffic generated from different services, e.g., voice and video, into a common service-independent framework. The GTC header carries an upstream bandwidth map, which includes information on transmission time slots allocated to each ONU. In the GPON, the bandwidth grant is per traffic container (T-CONT). A T-CONT is an ONU object representing a group of logical connections that appear as a single entity for the purpose of upstream bandwidth assignment on the PON. For example, a GPON may have multiple T-CONTs per ONU, each dedicated for a different traffic class, e.g., best-effort and high priority. The allocation ID (Alloc-ID) is used to identify uniquely a T-CONT.

Fig. 4 illustrates the upstream frame structure of GPON (ITU-T, 2008b). The frame length is as same as that of the downstream, 125 μ s and 19,440 bytes long. Each frame contains a number of transmissions from one or multiple ONUs, where the bandwidth map discussed under downstream frame structure schedules the arrangement of these transmissions. In any given upstream transmission, the ONU can transmit one of the four types of overheads and the payload. The four types of overheads are physical

Fig. 4 Upstream GPON packet structure. Adapted from ITU-T, 2008b. G.984 x-series recommendations: Gigabit-capable passive optical networks (G-PON): Transmission convergence layer specification (G.984.3).

layer overhead (PLOu), physical layer operations administrations and management upstream (PLOAMu), power levelling sequence upstream (PLSu), and dynamic bandwidth report upstream (DBRu). The ONUs utilize the dynamic bandwidth report (DBRu) field, located in the header of the upstream GTC frame, to inform the queue length of each T-CONT to the OLT.

Gigabit Ethernet PONs

The IEEE standardized the Gigabit Ethernet PON (GE-PON) under IEEE 802.3 ah (IEEE, 2004). Integrated with conventional Ethernet technology, GE-PON enables seamless integration with IP and Ethernet technologies. The GE-PON supports 1.25 Gb/s link rate in both upstream and downstream directions and a 20 km network span. The deployment of GE-PON is most prevalent in the Asian region, especially in countries such as Japan and Korea.

In GE-PON, Ethernet packets are transmitted natively across the PON. As Ethernet technology is widely deployed in current local area networks (LANs), incorporating Ethernet into PONs requires minimal protocol conversion as far as hardware and technical know-how are concerned. As a TDM-PON, the ONUs in a GE-PON follow a time division multiple access technique, where the upstream bandwidth is divided into distinct time slots. In order to obtain bandwidth requirement information as well as to grant bandwidth from and to each ONU, a GE-PON employs the Multi-Point Control Protocol (MPCP). MPCP relies on control messages to facilitate two modes of operation: auto-discovery and normal operation. The primary MPCP control messages used for each mode of operation are listed below:

- Auto-discovery: GATE, REGISTER REQ, REGISTER, and REGISTER ACK.
- Normal operation: GATE and REPORT.

Auto-discovery

Fig. 5 illustrates the auto-discovery process, an initialization process implemented at both OLT and ONUs. Using auto-discovery, the OLT identifies the MAC addresses and round trip times of ONUs that have recently joined the network (IEEE:802.3ah). For this purpose, MPCP uses four control messages, GATE, REGISTER REQ, REGISTER, and REGISTER ACK. When an OLT discovers new ONUs, it allocates a discovery window, where no other registered ONU can transmit. A discovery GATE message with a local OLT time stamp will be broadcast, which only the uninitialized ONUs will respond to. When an ONU clock reaches the start time of the discovery window, it will wait a random amount of time and send its REGISTER REQ to the OLT. The random delay minimizes potential collisions caused by multiple uninitialized ONUs simultaneously sending REGISTER REQ messages. The REGISTER REQ message contains the MAC address and the local time stamp of the ONU, through which the OLT learns the round trip time to the ONU. Once the ONU is registered, the OLT will assign a unique identification, link layer ID (LLID), to the ONU. The OLT will then send the unique LLID through REGISTER to the ONU. This is then followed by a normal GATE message. Upon receiving the REGISTER and normal GATE messages, the ONU sends the REGISTER ACK to the OLT during the time slot allocated through the normal GATE message.

Normal operation

Once ONUs have established their connection with the OLT, bandwidth requests from and allocations to each ONU are performed under normal operation mode, as illustrated in **Fig. 6** (Kramer, 2005). The GATE message, sent from the OLT to ONUs, is used to grant bandwidth (in the form of transmission time slots) to the ONUs. The GATE specifies the start time and the length of a transmission window and is sent per LLID. As discussed, an LLID which is attached to the preamble of the downstream packets, uniquely identifies an ONU in the network. The REPORT message, sent from each ONU to the OLT, contains bandwidth requirements of the ONUs. It is important to note that the standardized MPCP is not unique to a particular bandwidth allocation algorithm, rather, it is a supporting protocol that encourages the execution of different bandwidth allocation schemes in the GE-PON depending on latency, energy-efficiency, and capacity requirements of the network/service provider.

NG-PON1

Overview of 10GE-PON and XG-PON

The IEEE and the ITU-T with the Full Services Access Network (FSAN) group have defined their respective 10 Gb/s solution to address future bandwidth growth over existing ODNs that exploit time-division multiplexing (TDM) in the downstream direction and time division multiple access (TDMA) in the upstream direction. These solutions are specified in the IEEE Std. 802.3av 10 GE-PON (IEEE, 2009) and ITU-T XG-PON (ITU-T, 2010) standards respectively. The 10 GE-PON defines symmetric (10.3 Gb/s) and asymmetric (10.3 Gb/s downstream and 1.25 Gb/s upstream) line-rate operations, the latter to support asymmetric traffic of IP video services. In contrast, XG-PON1 supports an asymmetrical bandwidth capacity of 10 Gb/s downstream and 2.5 Gb/s upstream (ITU-T, 2010). In XG-PON1, new features including enhancing security through authentication of management messages and minimizing energy consumption through powering down parts or all of the ONU are defined. Specific solutions to minimize the energy consumption include (a) powering down user network interfaces that are not actively in use (b) operating in “doze” mode whereby the ONU transmitter is powered down when the user has no real data to send, and (c) operating in “sleep” mode whereby both transmitter and receiver are powered down when the ONU is idle. A symmetric version of XG-PON1, known as XG-PON2 with 10 Gb/s downstream/upstream capacity is also specified (ITU-T, 2010).

Forward error correction (FEC) is defined in both standards to compensate for the reduced receiver sensitivity from using 10 Gb/s optical receivers. NRZ line coding in conjunction with FEC ((RS(248,216) block code) is mandatory in the downstream

direction for XG-PON systems but optional in the upstream direction (ITU-T, 2010). For 10 GE-PON, FEC ((RS(255,223) block code) is mandatory for the symmetric network. As for the asymmetric 10 GE-PON network, the upstream 1 Gb/s links can optionally use the IEEE GE-PON FEC (IEEE, 2009). To enhance coding efficiency in 10 GE-PON, 64b/66b line coding is used instead of the conventional 8b/10b coding in GE-PON.

Coexistence and Wavelength Allocation

Table 1 summarizes the main characteristics of currently standardized TDM-PONs discussed in Sections Time-Division Multiplexed (TDM) Passive Optical Networks and NG-PON1. Coexistence between these different standards over the same ODN can be achieved by observing the wavelength allocation schematically shown in **Fig. 7**. In the figure, the upstream and downstream wavelength bands for XG-PON, 10 GE-PON, GPON, GE-PON, and RF video overlay are indicated. Specifically, GPON and GE-PON use 1480–1500 nm for downstream transmission and 1550–1560 nm for RF video overlay (ITU-T, 2008a; IEEE, 2004). For upstream transmission, GPON uses the 1290–1330 nm waveband whereas GE-PON uses the entire O band. Both XG-PON and 10 GE-PON specify the O-minus band (1260–1280 nm) for upstream transmission and the L-band (1575–1580 nm) for downstream transmission (IEEE, 2009; ITU-T, 2010), thus facilitating coexistence with legacy systems and those implemented with RF video overlay.

NG-PON2

Overview of Time and Wavelength Division Multiplexed-PON

The standardization process of NG-PON2 was implemented by ITU-T study group 15 (SG15) (ITU, 2013). To meet the general requirement of 40-Gb/s downstream capacity, an underlying hybrid time and wavelength division multiplexing scheme is adopted in NG-PON2, giving rise to the time and wavelength division multiplexing PON (TWDM-PON). **Fig. 8** depicts a typical schematic diagram of a TWDM-PON system (Luo *et al.*, 2013). Several wavelength pairs are multiplexed into a single PON system, whereby each wavelength is shared between multiple ONUs by employing time division multiplexing and multiple access mechanisms. NG-PON2 provides at least 40/10-Gb/s downstream/upstream capacity by stacking 4 TDM channel pairs with

Table 1 Comparison of standardized TDM-PONs

	<i>BPON</i>	<i>GPON</i>	<i>GE-PON</i>	<i>XG-PON1</i>	<i>10GE-PON</i>
Standard	ITU-T G.983	ITU-T G.984	IEEE803.2ah	ITU-T XGPON	IEEE 802.3av
Bandwidth

Fig. 8 TWDM-PON system diagram. Adapted from Luo, Y., Sui, M., Effenberger, F., 2012. Wavelength management in time and wavelength division multiplexed passive optical networks (TWDM-PONs). In: Proceedings of IEEE Global Telecommunications Conference (GLOBECOM).

10-Gb/s downstream and 10/2.5-Gb/s upstream capacity per channel. For seamless network upgrade and user migration, the optical technologies specified for NG-PON2 must be compatible to legacy PON systems, including the coexisting wavelength band plan and reusing the power splitting ODNs. As such, L band (1596–1603 nm) and C-band (1524–1544 nm) have been assigned for downstream and upstream transmission, respectively (ITU, 2013).

In addition, PtP-WDM channel overlay is defined in NG-PON2 for supporting services such as fronthaul and backhaul wireless network transmission with an expanded spectrum option of 1524–1625 nm and a shared spectrum option of 1603–1625 nm (ITU, 2013). Regardless, all specified PtP-WDM wavebands must be chosen from unused spectrum by the TWDM-PON and legacy systems. As for link budget, four ODN path loss classes are specified, namely Class N1, N2, E1 and E2, which corresponds to 29 dB, 31 dB, 33 dB and 25 dB respectively. The line code for both downstream and upstream links is scrambled NRZ. To improve receiver sensitivity, FEC support is mandatory at both OLT channel termination and ONU. For 2.5 Gb/s and 10 Gb/s, the FEC codes are RS (248, 332) and RS (255, 223), respectively.

In view of the multi-wavelength operation property of TWDM-PON, additional network and protocol requirements beyond that of legacy PON systems, are critical in TWDM-PONs, e.g., the ability to tune the ONU transmitter and receiver. In the upstream direction, the ONU is tuned to emit at the desired wavelength channel. In the downstream direction, a tunable ONU receiver is required to select the proper wavelength channel. Also, to eliminate the chromatic dispersion induced signal distortion, electrical dispersion compensation (EDC) may be used in the OLT/ONU to achieve the specified loss budget.

Energy-Efficient Dynamic Bandwidth Allocation

Aside from its increased bandwidth capacity, TWDM-PON is also an attractive solution from an energy perspective (Valcarenghi *et al.*, 2014; Dixit *et al.*, 2012). Due to multiple line cards and wavelengths channels, the power consumption of the OLT is comparatively higher in TWDM-PON compared to networks specified under NG-PON1. Nevertheless, the large number of ONUs serviced by the TWDM-PON results in lower energy per user. Considering its expected uptake, future-proofing the TWDM-PON in terms of energy-efficiency is becoming an important deployment factor.

As discussed before, a TWDM-PON consists of multiple wavelengths channels, requiring tunable ONU transceivers (TRXs) that can tune to any of the wavelength channels present in the network. Due to this tunability, at low network loads, the network may be reconfigured by switching off idle wavelengths and thereby saving energy at the OLT (Valcarenghi *et al.*, 2014). In addition, conventional power-saving methods such as sleep and doze can be implemented at the ONUs to improve overall energy-efficiency (Dixit *et al.*, 2012). As a result, recent energy-efficient solutions for TWDM-PON including dynamic wavelength and bandwidth allocation (DWBA) algorithms incorporating wavelength reconfiguration and sleep/doze mode operations, have been proposed.

One of the most important aspects of network reconfiguration through wavelength reallocation is determining how many wavelengths to be switched off without affecting the system performance. Optimizing the number of active wavelengths, subjected to different parameters of the network such as wavelength tuning time (Luo *et al.*, 2012), energy consumption (Yang *et al.*, 2011), or distance from the OLT (Dixit *et al.*, 2013), have been proposed as a result. Energy-saving techniques such as wavelength

reconfiguration and sleep/doze mode operations on the other hand, result in an increase in the average delay experienced by transmission packets. If the tuning time is assumed to be negligible, unlimited wavelength switching could be practised in a network. Although unlimited wavelength switching may theoretically result in significant energy-savings, in reality, the tuning time of an ONU is significant. In fact, the tuning time of an ONU transmitter can range from nanosecond to sub-second order while the ONU receiver tuning time can range from nanosecond to second order based on implementation (Asaka, 2014). It has also been shown that the ratio between the tuning time and the polling cycle time (Kondepu et al., 2014), and the OLT's awareness of the wavelength tuning time (Buttaboni et al., 2014) are strongly correlated to performance matrices. As such, when considering a TWDM-PON with non-zero wavelength tuning time, the improved energy-savings through wavelength reconfiguration will be achieved at the expense of increased average delay of the network. To overcome this shortfall, using the average delay as a constraint in wavelength optimization (Xu et al., 2015) and changing the polling sequences based on the wavelength tuning time (Wang et al., 2015), have been reported in literature.

Introducing sleep/doze mode operations into a wavelength-reconfiguring algorithm increases the average delay further. In the energy-efficient DWBA algorithm reported in Dias et al. (2015), the Quality-of-Service degradation is minimized using Bayesian estimation and prediction techniques. The proposed DWBA algorithm considers a delay-constrained TWDM-PON and determines the maximum polling cycle time, $T_{poll\ max}$ that satisfies a given delay constraint. The $T_{poll\ max}$ is considered to achieve maximum energy-savings at the ONUs through sleep/doze mode operations. Based on this $T_{poll\ max}$, the number of active wavelengths is determined and the remaining idle wavelengths are switched off to achieve energy-savings at the OLT. Under the proposed framework, $T_{poll\ max}$ for both online and offline DWBA algorithms are determined. Under the online DWBA algorithm, the OLT uses average inter-arrival time of packets, estimated using Bayesian estimation at the ONUs, to predict the accumulated bandwidth at each ONU. The proposed traffic estimation and prediction prevents the ONUs from waiting extra cycles, before being allocated any bandwidth for transmission. Fig. 9 illustrates the traffic flow of the proposed DWBA algorithm.

High Capacity TWDM-PONs

To accommodate the anticipated increase in customer bandwidth demand, NG-PON2 systems may support an optional extension for services in excess of 10 Gb/s upstream and/or downstream towards one PON client, as was specified in G989.1 amendment 1 (ITU, 2013). It was defined in the recommendation G.989 series that NG-PON2 system supports multiple wavelength channels and enables flexibility to add capacity as bandwidth demand is expected to grow to 100 Gbit/s and beyond (ITU, 2013). The cost-effective solution for capacity enhancement, such as realizing 25 Gb/s per channel is under hot discussion. Generally, 10 G-class optical devices have been preferred for cost control, thereby necessitating advanced modulation formats with higher spectral efficiency. Four-level pulse amplitude modulation (PAM-4) (Wei et al., 2015) and duobinary (Li et al., 2015) formats are the most promising format candidates, and based on these two modulation formats, many experimental demonstrations of 10 G-class devices enabled 25 Gb/s modulation have been reported. As the demodulation circuit for duobinary and PAM-4 formats are not yet commercially viable, signals are sampled by real-time oscilloscope and processed offline in most of these demonstrations. Several research groups have reported real-time demodulation for duobinary and PAM-4 formats, although further improvements are required for application in practical PON systems. To date, the reported real-time 25-Gb/s PON system demonstrations are mostly based on optical duobinary (ODB) format. Though the ODB format is robust to fiber dispersion, it necessitates costly Mach-Zender Modulators (MZMs) and wide-band receivers for modulation and detection.

Consequently, efforts in increasing the modulation bandwidth as well as decreasing the cost of both optical transmitters and receivers are underway. Related works are being reported, e.g., 30-GHz directly modulation DFB laser (Zhang et al., 2015), 25-Gb/s

Fig. 9 Traffic flow of the OFF-DWBA algorithm. D-Data, R-REPORT and G-GATE. Dias, M.P.I., Van, D.P., Valcarenghi, L., Wong, E., 2015. An energy-efficient framework for wavelength and bandwidth allocation in TWDM PON. J. Opt. Commun. Netw. 7(6) 496–504.

Si-Ge APD (Huang *et al.*, 2016), and bandwidth improvement of CMOS-APD (Lee *et al.*, 2015), etc. Signal distortion from fiber chromatic dispersion is another issue to be handled, especially for high-speed signal, and some institutes are studying the proper dispersion compensation techniques for high data rate signal. With the development of wide-band transceivers and practical dispersion compensation techniques, NRZ format can still be a potential candidate for high capacity PON applications.

Future PONs

Wavelength Division Multiplexed PONs

The WDM-PON has been touted as a long-term access solution beyond TDM-PONs. The system operation of a WDM-PON is entirely different to the TDM-PON whereby in the former each ONU located in a home/office/building is assigned its own upstream and downstream wavelength channel. This is contrary to more a traditional PON architectures where one optical feed is shared among 32 or more users. In that case, each home operates at the same wavelength, and is allotted a 1/32nd time slot on the main fiber. In a WDM-PON, each home/office/building is assigned its own wavelength and has continual use of the fiber at that wavelength. However, virtually all PON technologies rely on some form of wavelength division multiplexing (WDM) to enable bi-directional communications. For example, in a typical GPON system, the upstream communication runs at 1310 nm wavelength, while the downstream traffic is transmitted at 1490 nm. A third wavelength at 1550 nm is used for video overlay. The utilization of WDM in PON systems is therefore already very commonplace.

Fig. 10 illustrates a typical WDM PON comprising a CO with an OLT, two cyclic AWGs, a trunk or feeder fiber, a series of distributions fibers, and ONUs at the subscriber premises (Wong, 2012). Downstream wavelengths and upstream wavelengths from the ONUs are multiplexed and demultiplexed in the AWG located at the CO. These wavelength channels also under (de) multiplexing at the AWG in the remote node located closer to the ONUs. The trunk fiber carries the multiplexed downstream and upstream wavelengths between the first and second AWG. The distribution fiber carries the demultiplexed wavelengths to and from the remote node to the ONUs. Both AWGs have the same free spectral range (FSR). Note that the downstream and upstream wavelengths allocated to each ONU are intentionally spaced at a multiple of the FSR, allowing both wavelengths to be directed in and out of the same AWG port that is connected to the destination ONU. For example, the downstream wavelength destined for ONU1, denoted λ_1 , and the upstream wavelength from ONU1 denoted $\lambda_{1'}$, are spaced a multiple of the FSR. In a typical WDM PON, wavelength channels are spaced 100 GHz (0.8 nm) apart. In systems classified as dense WDM-PON (DWDM), a channel spacing of 50 GHz or less is deployed.

There are several advantages to the WDM-PON architecture over more traditional TDM-PON systems. Foremost is the dedicated bandwidth available to each ONU. Secondly, WDM-PONs can typically have improved security and scalability features, because each ONU only transmits and receives on assigned wavelength channels. Thirdly, the MAC layer in a WDM-PON is simplified, since the logical topology of a WDM-PON is a PtP topology between the OLT and each ONU, and thus does not require the use of PtMP media access controllers found in conventional TDM-PON networks. Finally, each wavelength in a WDM-PON network is effectively a PtP link, allowing each link to operate at a different speed and if required a different MAC protocol for maximum flexibility and pay-as-you-grow upgrades.

The main challenge with WDM-PON is the cost. Since each ONU is assigned his own wavelength, this suggests that the OLT must transmit on different wavelengths versus one shared wavelength as found in more traditional TDM-PON systems. Likewise, it requires that each of the ONUs on a link operate at a separate wavelength, suggesting that every ONU requires a wavelength-specific laser that can operate at its assigned wavelength. Since each ONU is assigned a unique upstream wavelength channel,

Fig. 10 WDM-PON. Inset: Allocation of upstream/downstream wavelength into two separate wavebands. Reproduced from Wong, E., 2012. Next-generation broadband access networks and technologies. IEEE/OSA J. Lightw. Technol. 30(4), 597–608.

distinct wavelength transmitters must be deployed at the subscriber premises. The simplest solution is to utilize fixed wavelength transmitters with wavelength tunability, e.g., tunable distributed feedback (DFB) laser (Suzuki *et al.*, 2007), tunable vertical cavity surface emitting lasers (VCSELs) (Wong *et al.*, 2006), and distributed Bragg reflector laser diodes (DBR-LDs), such as sampled grating DBR-LDs and super structure grating DBR-LDs (Kuвано *et al.*, 2001; Ishii *et al.*, 1996).

Alternatively, wavelength reuse schemes that eliminate optical sources at the ONUs have been proposed. Aside from carrying downstream signals, the downstream wavelength is used to wavelength seed a reflective semiconductor optical amplifier (RSOA) located at the designated ONU. The RSOA is intentionally operated in the gain saturation region whereby the RSOA amplitude squeezing effect can be exploited to erase the modulation on the seeding downstream wavelength (Katagiri *et al.*, 1999). Wavelength reuse schemes eliminate the need for seeding sources, is less costly than using tunable lasers, and allows direct modulation of the RSOA for upstream transmission. The drawback is severe performance degradation at the CO due to interference between the newly modulated upstream data and residual downstream data. A solution to improve transmission performance is through using orthogonal upstream and downstream modulation formats (Garces *et al.*, 2007) and line coding approaches (Kim *et al.*, 2007; Al-Qazwini and Kim, 2011).

In addressing the potential large inventory and cost of wavelength specific sources, researchers have been concentrating on developing cost-efficient and wavelength independent sources termed “colorless” sources. These sources include directly modulated light-emitting diode (LED) and super-luminescent diode (SLD) (Reeve *et al.*, 1988) which broadband spectrum from each ONU is spectrally sliced by the AWG in the upstream direction. These sources are limited in terms of system reach and modulation bit rate. In yet another category of colorless sources, optical light originating from the CO is fed into the ONUs to injection-lock Fabry-Perot laser diodes (F-P LDs) (Kim *et al.*, 2000) or to wavelength-seed RSOAs (Feuer *et al.*, 1996). The wavelength seeding scheme is identical to the injection-locking scheme except for the use of an RSOA which amplifies and modulates the incoming continuous wave (CW) light. The drawback of these schemes lie in the requirement of additional broadband light source(s), limited transmission bit-rate due to device limitation, and susceptibility to transmission performance impairment from fiber dispersion, Rayleigh backscattering noise, and broadband amplified spontaneously emission (ASE) noise from the broadband light source and the colorless source.

More recently, self-seeding of the RSOA was proposed in which each RSOA is self-seeded by its own spectrally-sliced CW light (Wong *et al.*, 2007). ASE light emitted from each RSOA is spectrally-sliced by the AWG located at the remote node and feedback to the RSOA. Self-seeding removes the need for active temperature tracking between the optical components within the remote node and between the remote node and each RSOA and identical RSOAs can be placed at all ONUs.

Extended-Reach PONs

ER-PONs can serve an increased number of subscribers, accommodate high bandwidth applications, and an increased network span that consolidates metro and access networks. This consolidation lowers capital expenditure (CAPEX) and operational expenditure (OPEX) due to a reduction in the number of active network interfaces and elements in the field. The idea of extending the reach of a PON is not new with many significant demonstrations and field trials carried out in the 1990s (Mestdagh and Martin, 1996). However, advances in optical amplification and WDM technologies in recent years along with the volume manufacturing of optical components such as SOAs, AWGs, and WDM filters, have lowered the cost of ER-PONs to a point that is competitive in the business and access market.

An illustrative example of an ER-PON is shown in Fig. 11 whereby multiple COs which were previously connected to a metropolitan aggregation ring network (dash line) are now consolidated at the main central office (MCO) to support a large

Fig. 11 Schematic diagram of a two stage extended-reach PON (ER-PON) showing consolidation of central offices (COs) previously connected to the metropolitan aggregation ring network at the main central office (MCO). Reproduced from Wong, E., 2012. Next-generation broadband access networks and technologies. *IEEE/OSA J. Lightw. Technol.* 30(4), 597–608.

number of customers via remote nodes. The ODN of a typical ER-PON comprises an extended-reach FF which connects the MCO to remote node 1 (RN1), DFs which connect RN1 to remote node 2 (RN2), and last mile fibers (LMFs) that connect RN2s to customers. Bandwidth-dedicated business customers and mobile customers can be connected directly to RN1 whereas residential users can be connected to RN2. By exploiting a combination of (a) TDM or WDM in the first stage, and (b) TDM in the second stage, system reach can be extended from the conventional 20 km to 60–100 km while maintaining a 1:32 or higher split ratio. In case where the first stage is based on TDM, a single upstream and downstream wavelength support all users with power splitting carried out in both RN1 and RN2s. When the first stage is based on WDM, wavelengths are multiplexed at the MCO and transmitted simultaneously through a feeder fiber to RN where optical amplification and demultiplexing take place. In turn, in the second stage of the ER-PON, each demultiplexed wavelength is then further power split at RN2 and then transmitted to multiple customers. A reach extender is typically housed in RN1 to compensate for power loss due to the long transmission distance and high split ratio.

A few reach extended technologies have been proposed to compensate for the insertion loss of ER-PONs. These include optical amplification at the MCO and/or RN1, using erbium doped fiber amplifier (EDFA) (Townsend *et al.*, 2008), SOA (Suzuki and Nakagawa, 2005), and distributed Raman amplification (DRA) (Kjaer *et al.*, 2006). EDFAs provide excellent gain power and noise performance in the C and L-bands. However, optical amplification is limited to these wavelength bands and unless gain control through optical gain clamping or pump power variation is implemented, the relatively slow speed in adjusting the EDFA gain makes this option disadvantageous to the bursty nature of upstream TDMA traffic. The SOA, on the other hand, benefits from the fact that it can operate at any wavelength of interest including the O band and with better gain dynamics than the EDFA. Other benefits include compactness and the ability to facilitate additional functionalities such as wavelength conversion and all-optical regeneration. However, the SOA operates on a per-channel basis. The inability to provide simultaneous amplification across multiple channels is its main drawback. The use of DRA in counter and co-propagation configurations enables amplification across a wide wavelength region over a bidirectional fiber link. Raman amplifiers can be tailored to provide a flat optical gain bandwidth that encompasses wavelengths exceeding those of common optical amplifiers. Using simultaneous launching of multiple pump wavelengths, DRA can achieve a flat Raman gain of up to 100 nm of bandwidth. Combining the benefits of EDFA and SOA, DRA allows simultaneous multichannel amplification, fast gain dynamics, and the ability to provide gain at any wavelength contingent on the pump wavelength. Using DRA does however require high pumping power, thereby adding to the power consumption at the RN1 and MCO.

In replacement of optical amplification, electronic repeater(s) can be implemented at RN1 to facilitate 1R or 2R regeneration of both upstream and downstream signals (Davey *et al.*, 2009). In using electronic repeater(s), benefits include the option of wavelength conversion, bit-error-rate monitoring, and optical power equalization of the burst mode signals in the upstream direction. However, a drawback of electronic repeaters is the need for bit-rate specific burst mode receivers that must also be capable of handling a wide dynamic range.

Orthogonal Frequency Division Multiplexing PON

Orthogonal frequency division multiplexing (OFDM) is a modulation technique which is now used in most new and emerging broadband wired and wireless communication systems (Cvijetic, 2012). In OFDM, the spectra of individual subcarriers overlap as depicted in Fig. 12(a), but the signals on each subcarrier are mathematically orthogonal over one OFDM symbol period. As such, the subcarriers can be demodulated without interference. Dispersion-induced signal distortion can be eliminated by adding a cyclic prefix (CP) to the start of each time domain OFDM symbol before transmission, i.e., a number of samples from the end of the symbol is appended to the start of the symbol as shown in Fig. 12(c) (Armstrong, 2009), by which any distortion caused by a linear dispersive channel can be corrected simply using a ‘single-tap’ equalizer. Also, by employing bit-loading techniques, the modulation formats on each subcarrier can be different according to the channel response. Combined with the time- and frequency-domain multiplexing as shown in Fig. 12(b) (Qiu *et al.*, 2011), data can be assigned to end-users by different time slots or subcarriers with different modulation formats, thereby supporting a flexible 3-dimensional (3D) dynamic bandwidth allocation algorithm.

Despite advantages such as high spectral efficiency, high dispersion tolerance, and flexible bandwidth allocation, thus making OFDM a suitable modulation technique for future high-capacity PON systems, its drawbacks mainly due to high peak to average power ratio (PAPR) and high sensitivity to phase noise and frequency offset, easily degrades performance and limits its practical application. Digital signal processing (DSP) algorithms are being proposed to reduce PAPR (Popoola *et al.*, 2014) and to mitigate signal distortion caused by phase noise and frequency offset (Yi *et al.*, 2008). However, as high-speed ADC/DAC and complex DSP algorithms are required for the generation, demodulation and equalization of high-speed OFDM signal, most of the experimental demonstrations are realized off-line. Further, the capacity of the demonstrated real-time systems is generally lower than 10-Gb/s per channel. Another drawback of OFDM modulation is its low sensitivity. With the modulation format of 16-QAM or even higher, the sensitivity of directly-detected signal is much lower than the traditional NRZ format, thereby severely limiting the loss budget of the PON system. To solve this problem, coherent detection is introduced in OFDM-PONs to improve receiver sensitivity. As a result, the loss budget is increased at the cost of a higher system complexity.

So in the short term, limited by the cost of high-speed ADC/DAC and the complex DSP modules, OFDM-PONs are still considered an expensive option. However, with the emergence of novel applications, low spectral-efficiency formats such as NRZ

Technol.* 27(3), 189–204 and Qiu, K., Yi, X., Zhang, J., *et al.*, 2011. OFDM-PON optical fiber access technologies. In: Asia Communications and Photonics Conference Optical Society of America, 1–9.

Fig. 13 Evolution of broadband passive optical access networks.

and RZ, will not be able to satisfy the increase in bandwidth demand and ultimately, and the spectral-effective OFDM-PON will be a solution by then.

Summary and Conclusion

A brief overview of the evolution of passive optical networks with particular focus on standardized systems mentioned, and the emerging trends to address future bandwidth needs, was discussed in this article. This summary of the evolution of PONs is illustrated in Fig. 13. Driven by the increasing user bandwidth demand for emerging applications, PONs with increasing capacity and cost-efficiency have been deeply discussed and studied around the world. BPON, GPON, XG-PON have been standardized by ITU, while GE-PON and 10GE-PON have been standardized by IEEE. These technologies are all developed by gradually increasing the data rate. The main reasons behind the push for these TDM/TDMA PON systems are to extend the longevity of existing ODNs and to allow co-existence with the current generation PONs such that the operational impact on existing users will be minimized.

Due to the chromatic dispersion and cost issues, only increasing the data rate per wavelength is more difficult and encounters some bottlenecks especially when the bit rate is beyond 10 Gb/s. In order to increase the system capacity, NG-PON2 employs the technique of stacking wavelength, called as TWDM-PON, which has been standardized by ITU-T in 2015 and is supposed to be commercially available in around 2018. From 2016, IEEE next generation Ethernet passive optical network (NG-EPON) has also been discussed in-depth to provide a capacity of 100-Gb/s with 25-Gb/s per wavelength, which has attracted extensive attention from the industry. In the future, in order to satisfy the bandwidth requirement, more advanced technologies will be proposed to upgrade the system capacity such as OFDM-PON and WDM-PON. High-speed PON with higher data rate per wavelength is also an effective solution to increasing the system capacity. So the combination of stacking more wavelengths and increasing the data rate of per wavelength or using complicated technologies such as coherent detection and digital signal processing will be effective solutions to overcome the problem of system capacity. In order to successfully deploy these technologies, the implementation complexity must be minimized to a level that is comparable to existing commercialized systems and with a cost that is sufficiently low to meet the cost constraints of the access market. In all PON with higher capacity and lower cost will be the ultimate goal from both industry and academia.

Holographic Recording Media and Devices

Pierre-Alexandre Blanche, The University of Arizona, Tucson, AZ, United States

Holography Terminology

Holographic recording materials are able to change their refractive index and/or their absorption according to the intensity pattern created by two interfering laser beams. Then, when the material is re-illuminated by the appropriate light, the material can diffract the incoming beam and display the hologram. Thus, there are two functions that the material must perform: sensitivity to the recording light, and physical transformation of the optical properties.

The distinction between an image recording material and a holographic recording material is their necessary spatial resolution. For imaging, the material only needs to resolve details down to tens of microns, so the image is detailed and sharp to the human eye. For holography, we need to reproduce the modulation obtained by the interference between two laser beams. In this case, the separation between bright and dark regions can be sub-micron scale. This is the reason why digital holography had to wait for the development of high-pitch focal-plane-array sensors to become practical.

The goal of this entry is not to explain holography. However, since it heavily relies on the terminology associated with this method, it is necessary to give a brief introduction on the most important techniques.

When the material records the hologram as an absorption modulation, one talks of an amplitude hologram, since it is the amplitude term of the light wave that is affected when interacting with the media. When it is the index of refraction of the material that is modulated by the recording, one talks of a phase hologram. In this latter case, there is no absorption of the incident light, and the efficiency of the hologram can be larger than for an amplitude hologram.

Holograms can also be recorded by modifying the surface of the material, such as by scribing or by lithography. In this case, the hologram is also a phase modulator, due to the difference in light path.

Another distinction with holograms, is they are either transmission or reflection holograms. With transmission holograms, the incident light goes through the medium and is diffracted on the other side of the material. The Bragg planes in this case are oriented more or less perpendicular to the surface of the material. For reflection holograms, the light is diffracted back toward the same side of the material as the incident beam. In this case, the Bragg planes are roughly parallel to the surface of the material.

There is an important difference between the spectral and angular properties of transmission and reflection holograms. Transmission holograms are angularly selective but spectrally dispersive, which means that when illuminated with a white light (broad band source) they diffract the incident light into a rainbow (the spectrum is dispersed). However, when transmission holograms are illuminated with a monochromatic source, they will only diffract at a very specific angle of incidence, the Bragg angle (angular selection).

The behavior of reflection holograms is quite the opposite: they are spectrally selective and angularly tolerant. Illuminated with a white light, they only diffract back a specific color, acting like a filter (spectral selection). However, reflection holograms can diffract the incoming light over a large angle of incidence.

Beware that a reflection coating can be applied to a transmission hologram to make it look like a reflection hologram: the light will be diffracted back. However, its spectral and angular characteristics will still be that of a transmission hologram.

There exist two regimes of diffraction: Raman-Nath and Bragg. The Raman-Nath regime is characterized by having a significant amount of energy not diffracted by the hologram (strong zero order), and diffracted into orders higher than 1: ± 2 , ± 3 , etc. This happens when there is only a short distance of interaction between the light and the hologram. Holograms operating in that mode are also called "thin", even though the actual thickness of the material is only one of several parameters defining the regime. On the other hand, when in the Bragg regime, holograms diffract most of the energy into the first order. For this to happen, the interaction length between the light and the grating should be relatively long, so these holograms are called "thick". The specific criteria between these two regimes is not just the physical thickness (d) but involves the light wavelength (λ_0), the material index of refraction (n), the grating spacing (Λ), and the angle of incidence (θ) in the Klein and Cook relationship:

$$Q' = \frac{2\pi\lambda_0 d}{n\Lambda^2 \cos\theta} \quad (1)$$

where $Q' < 1$ for the Raman-Nath regime, and $Q' > 1$ for the Bragg regime.

Another criteria for the energy distribution in higher orders is the Moharam and Young equation involving the index modulation (Δn):

$$\rho = \frac{\lambda_0^2}{n\Delta n\Lambda^2 \cos\theta} \quad (2)$$

where $\rho < 1$ for the Raman-Nath regime, and $\rho \geq 1$ for the Bragg regime.

We now need to introduce the different figures of merit characterizing a holographic material:

Sensitivity: sensitivity is the most important criteria defining the amount of energy density in J cm^{-2} units required to achieve a certain amount of efficiency. The sensitivity figure is generally not divided by the efficiency (J cm^{-2}) but given for a specific

efficiency (e.g., J cm⁻² @ 90%). The sensitivity can also be given as the modulation (either index of refraction (Δn) or absorption ($\Delta \alpha$)) according to the energy density. The sensitivity generally depends of the wavelength used to record the hologram, which brings us to the next figure of merit the spectral sensitivity.

Spectral sensitivity: spectral sensitivity is the range of wavelengths to which the material is responsive, and holograms can be recorded. Ideally, it should be a curve of the sensitivity according to the wavelength, but most of the time there is only indication for the main laser lines: krypton red 647 nm, HeNe red 633 nm, argon green 514 nm, doubled YAG green 532 nm, and cadmium blue 441 nm. When a material has a very limited spectral sensitivity confined in only one color, it is called monochromatic. When the material is sensitive to red, green, and blue, even if only at very specific laser lines, it is called panchromatic.

Maximum efficiency ($\eta_{\max}$): maximum efficiency ($\eta_{\max}$) is the maximum diffraction efficiency expressed either as the ratio between the first order diffracted intensity divided by the incident intensity (external efficiency), or the ratio between the first order diffracted intensity and transmitted intensity without hologram (internal efficiency). Note that since the transmitted intensity is already reduced by the absorption, scattering, and Fresnel reflections from the material, the internal efficiency is always larger than the external efficiency.

Maximum modulation: maximum modulation is the maximum index (Δn) or absorption modulation (Δa) of the material. The maximum modulation is important to determine the diffraction efficiency. Recording geometry and wavelength are also important in that regard, but as a rule of thumb, longer wavelengths require larger modulation. Also the maximum modulation is important to consider when multiplexing several holograms into the same material. In this case, each of the multiplexed holograms takes a fraction of the maximum modulation range.

Spatial resolution: spatial resolution is the range of lateral frequencies the material is able to record and reproduce. When plan waves interfere, they produce intensity fringes spaced according to the grating equation:

$$\Lambda = m \frac{\lambda_0 / n}{\sin(\theta_d) - \sin(-\theta_i)} \quad (3)$$

Where Λ is the fringes spacing, m the diffraction order, λ_0 the wavelength of the light, θ_d the diffraction angle, and θ_i the incidence angle, with both angles being defined by the recording geometry. This spacing ranges from a few hundred line pairs per millimeter (lp mm⁻¹) for low angle transmission hologram, to several thousand for reflection holograms at small wavelength (blue). An image hologram can be decomposed as the superposition of a multitude of these plane waves (Fourier decomposition). The material should be able to reproduce these small features in order to reproduce the hologram with maximum angular resolution.

Illumination Dynamic Range

The interference pattern is composed of an intensity modulated structure. So the material must be able to react not only to a certain average level of light (sensitivity), but reproduce an entire range of intensity. The dynamic range is given by the maximum and minimum intensity the material can react to. If the minimum intensity is not zero, the intensity ratio between object and reference beams can be detuned to accommodate the minimum.

Illumination Linearity Response

Within the dynamic range, it is expected that the material reacts linearly to the intensity. Thus, if the fringe pattern is sinusoidal, the modulation is also sinusoidal. If this is not the case, the phase or intensity modulation inside the material introduces higher spatial frequencies which translate into more energy directed into higher orders and a loss of intensity in the ± 1 order.

Stability: stability can be understood as the shelf life of the material before exposure, or the lifetime of the hologram once it has been processed, which are different and has to be specified. In any case, the stability of the material depends on environmental conditions such as temperature, humidity, and UV exposure.

Absorption spectrum: absorption spectrum is the absorption coefficient (cm⁻¹) as a function of wavelength. Unexposed material should have some absorption in order to interact with the recording light (sensitivity spectrum). However, it is important that once processed, the material be as transparent as possible for the waveband of interest. Absorption reduces the external efficiency.

Scattering: scattering in addition to the absorption some loss can be due to scattering. The dispersion is mostly due to inclusions in the material whose size is comparable to the wavelength of light, resulting some Mie scattering. Scattering can be due to micro-bubble formation such as in gelatin emulsion material, or polymer crystal formation such as in photopolymer. These problems will be detailed in the specific material sections.

Thickness change: When the material is processed after exposure, it can experience some thickness change, either shrinkage or swelling. This volume modification reshapes the Bragg's planes by tilting them and imposing a different grating spacing. The tilt changes the diffraction angle and the modification of the spacing affects the diffracted wavelength. Both changes can be computed according to the grating equation (Eq. (3)).

Pulse response: The energy delivered for recording the hologram can be such as a long exposure at relatively low intensity, or as a short pulse with high peak power. Laser pulses can be formed to last several hours (CW), or as short as picosecond, femtosecond, or even attosecond pulses. For a given energy, when the duration of the pulse decreases, the peak intensity increases proportionally. Depending on the mechanism involved to record the hologram in the material, there is a peak power, or a pulse

duration, for which this mechanism is less efficient or changes entirely. At that moment, there is a reciprocity failure in the sensitivity of the material.

Permanent Materials

One can claim that any material can be used to permanently record a hologram; it all depends of the recording energy. In this section we will focus our attention on the most sensitive and widely-used materials today.

Between the recording and display steps, permanent holographic materials need to be processed to enhance the phase or amplitude modulation that have been initiated by the exposure. This post-processing changes the nature of the material and fixes the hologram permanently. This means that new holograms cannot be recorded with further exposure of the material, and the hologram(s) already present cannot be modified.

Permanent holographic recording materials are the first to have been explored, and their development is closely related to the photographic recording medium. They are still developed today due to the large demand for long lasting holographic images, either for the security tag industry (bank notes and anti-counterfeit product), art work, holographic optical elements such as notch filters, dispersion gratings and null testers, or, to a lesser extent, holographic data storage.

Silver Halide

The chemistry of silver halide material is similar to the one used in analog black and white photography. Both of them use a colloidal suspension of silver halide crystals such as AgBr, AgCl, and AgI in gelatin, and require a post-exposure wet processing to make the image/hologram appear. This wet process presented in Fig. 1, uses a developing agent that enhances the latent image by transforming the entire silver halide crystal that has been exposed into an opaque metallic silver particle. The developer bath is followed by a stop bath to halt the reaction, then a fixer bath that removes the remaining unaltered silver halide crystals. At this point the picture/hologram is a gray scale (amplitude modulation) reproduction of the intensity distribution that illuminated the material).

There are two differences between the photographic and holographic material: the size of the crystals, which influences both the spatial resolution and the sensitivity; and the bleaching process, which is used in holography to transform the amplitude modulation into phase modulation and enhance the efficiency.

The size of the features to resolve in the case of a hologram (tens of nanometers) is orders of magnitude smaller than in a case of visual photography (tens of microns). Therefore, the grain size of the silver halide crystal used for hologram recording should be much smaller than for visible photography. In this regard, the holographic plates are similar to the ones used for X-ray medical applications. The sensitivity of silver halide is directly proportional to the size of the grain. So, the holographic emulsions are much less sensitive than the photographic one. For example, an emulsion able to resolve 5000 lp cm^{-1} has a grain size of 10 nm and a sensitivity of a few mJ cm^{-2} .

When the emulsion is processed to generate an amplitude modulation, its diffraction efficiency is limited to a maximum of 3.7% due to the resulting average absorption. It is possible to enhance the efficiency up to 100% by transforming this amplitude modulation into a phase modulation. This transformation is done by another wet post-processing called the bleaching process that is applied in addition to the traditional developer and fixer baths. In this bleaching process, the remaining silver particles are dissolved and leave voids with lower index of refraction than the surrounding gelatin (Fig. 2).

Fig. 1 Exposure and post processing of silver halide emulsion for amplitude modulation.

Fig. 2 Transformation of the amplitude modulation (absorption) into phase modulation (refractive index) by bleaching.

The advantage of silver halide emulsion is: a very large spectral sensitivity that covers the entire visible region (panchromatic) and even part of the infrared. This spectral sensitivity allows the recording of full color reflection holograms. Silver halide emulsions also have a very good sensitivity in the order or better than mJ cm^{-2} . This sensitivity is especially valuable when compared to other holographic recording materials that require much higher energy density. The spatial resolution of silver halide could be made such that it allows the recording of both transmission and reflection holograms. However, there is a trade-off between the spatial resolution and sensitivity. So, a careful selection of the emulsion according to the application is advised.

The disadvantages of silver halide material are the relative complexity of manufacturing and processing. Indeed, the chemistry, the application of the emulsion, and the careful handling in dark room, make silver halide a complex material to fully master. Other disadvantages are the limited shelf life, the material shrinkage during processing, and the possible scattering that occurs due to the bleaching process. This scattering is caused by the relatively large size of the voids left when the silver grains are removed, leaving some haze when the holographic image is rendered.

The shrinkage of the emulsion is particularly inconvenient for the production of reflection holograms. Any material thickness change between recording and display induces chromaticity change, and to a lesser extent, optical aberrations. It is possible to control, and even take advantage of the shrinkage by both pre and post processing, but this requires fine-tuning of the procedure.

For further reading about silver halide emulsion for holography see [Bjelkhagen \(1993\)](#).

Dichromated Gelatin

Dichromated gelatin (DCG) is quite similar to silver halide. The medium in both cases is gelatin, which is mainly composed of collagen, a natural protein, and both materials can produce very efficient phase holograms. However, in the case of DCG, the sensitizer is ammonium dichromate $(\text{NH}_4)_2\text{Cr}_2\text{O}_7$ (potassium dichromate is sometime used $\text{K}_2\text{Cr}_2\text{O}_7$), which is easier to obtain than fine silver halide crystals. The trade-off for this easier manufacturing is that both sensitivity and spectral response of the DCG are more limited than silver halide. DCG usually requires exposure in the order of several mJ cm^{-2} and is only sensitive to the blue and green region of the spectrum with a response of about 1–5 for these different wavelengths (1:488 v 5:532 nm). Sensitization of gelatin in the red has been demonstrated using other colorants, such as methyl blue, but this requires even higher energy exposure.

This requirement for large energy means that DCG needs high power lasers for the recording, or longer exposure time. Longer exposure time puts high constraints on the stability of the setup, and eventually a phase stabilization system could be required.

Once the material has been exposed, the dichromate is removed from the emulsion by a fixer bath and rinsed with water. The water also swells the gelatin, which creates larger voids where the gelatin was not exposed. The exposure has cross-linked the collagen molecular chains of the gelatin making it harder. The water is then removed by successive baths of increased concentration of isopropyl alcohol, to end up with a 100% concentration alcohol final bath. After processing, the gelatin film is fully transparent through all of the visible spectrum, as it should no longer contain any dichromate.

The index modulation of the DCG hologram can be finely tuned by:

- The aging of the material before or after exposure, old material is harder and has lower index modulation.
- The exposure energy, very low or high exposure leads to lower index modulation.
- The development process. In this final case, the temperature of the water bath is particularly critical. Higher temperatures produce a higher index modulation.

The modulation can be increased to up to 10% of the average index, which is one of the highest index modulation for any holographic recording material. Past that point, the size of the voids causes Mie scattering and the gelatin film becomes hazy.

In the case when the developing process did not produce the desired index modulation, the gelatin can be reprocessed starting at the water bath, reducing or increasing the modulation by changing the temperature of the water. This is particularly useful when manufacturing dispersing elements where the blaze and superblaze curves (dispersion spectrum) need to be finely tuned.

Yet another advantage of the DCG is its spatial resolution. For silver halide the resolution is determined by the size of the crystals. For DCG, the resolution is due to the photo-reduction of the chromium ions, so resolution up to $10,000 \text{ lp mm}^{-1}$ can be achieved.

To avoid water re-absorption by the gelatin once it has been processed, it can be encapsulated between glass plates using optical glue. The gelatin media is particularly resistant to UV and thermal degradation.

For more information about DCG, see [Stojanoff \(2011\)](#).

Photopolymers

This group of materials are organic synthetic media that undergo a polymerization initiated by the illumination. In addition to this polymerization, the photopolymers also experience a change of refractive index, so the hologram is recorded as a phase modulation. This change of refractive index is not directly due to the polymerization, but rather to the diffusion of the remaining monomers to the polymerized regions. This diffusion by osmosis locally increases the density of the material in these regions and increases the index. When the modulation reaches the desired value the diffusion process can be halted by fully polymerizing the material, which can be achieved by UV illumination or thermal treatment (heating) depending of the material formulation.

The holographic recording process in photopolymer is presented in [Fig. 3](#) where the three steps: photo-polymerization, diffusion, and final polymerization are illustrated.

Fig. 3 Holographic recording process in photopolymer.

The sensitivity of photopolymers is on the order of 10 mJ cm^{-2} and they can be sensitized to respond to the entire visible spectrum. The spatial resolution can reach up to 4000 lp mm^{-1} , and the amount of shrinkage is minimal between recording and full polymerization, which is extremely useful for accurate color reproduction. Photopolymer also benefit from a prolonged shelf life and most formulations can be kept in the dark for years without any alteration. Very old samples (5+ years) have shown some crystallization though.

Commercially available photopolymers are the simplest holographic recording material to use. The post processing by UV illumination can be accomplished by direct sunlight exposure, and does not require a dedicated source.

The disadvantage of using commercial photopolymers is the inability to control the thickness of the material, which can be an important factor for dispersive elements. Also the backing medium that encapsulates the material is not under the control of the user, and in some cases has been reported to induce birefringence.

For more information about photopolymers, see [Guo et al. \(2012\)](#), as well as [Berneth et al. \(2011\)](#).

Photoresists and Embossed Holograms

The photoresists used for holography recording are the same materials as the one used by the semiconductor industry for lithography. Once exposed to light, the photoresist changes its ability to be dissolved by a solvent. One can distinguish between the positive resist where the parts illuminated become soluble, and the negative resist where the parts illuminated becomes insoluble. For holography this means that in both cases the modulation recorded is a surface relief.

The surface relief modulation can be used as a holographic pattern without any further modification. In this case, the hologram is used in transmission and the optical path length difference is given by the thickness modulation times the difference between the index modulation of the material and the air. The surface relief can also be coated with a reflective material such as metal. In this case the hologram is used in reflection and the path length difference is twice the thickness modulation.

The most common use for photoresist is to be a master copy for embossed hologram recording. The process is presented in [Fig. 4](#), where the surface relief structure of the photoresist is copied by electroplating. During electroplating, a thick layer of metal is grown on the top of the structure. This metal is used as a stamp to reproduce the relief in a heated thermoplastic material by embossing. The thermoplastic material is then coated with metal and further encapsulated by a protective layer. This process is used for mass producing holograms such as security tags for credit card or as an anti-counterfeiting measure for luxury items.

Because most photoresists have been developed for the photo-lithographic process, they have been optimized for short wavelengths such as UV light where smaller details can be imaged. Photoresist spectral sensitivity decreases dramatically at longer wavelength, such as in the visible. The holographic structure can be recorded by the interference of two UV laser beams, but more frequently it will be transferred to the photoresist by a lithographic process, either UV mask exposure, or by direct beam writing.

For more information about photoresist, see [del Campo and Greiner \(2007\)](#).

Photo-Thermo-Refractive Glasses

Photo-thermo-refractive Glasses (PTRG) are inorganic glasses such as $\text{Na}_2\text{O} - \text{ZnO} - \text{Al}_2\text{O}_3 - \text{SiO}_2$ doped with silver (Ag), cerium (Ce), and/or fluorine (F) atoms. These glasses are highly transparent in the visible and infrared (from 350 nm to 2700 nm), but UV exposure below 350 nm followed by thermal precipitation of crystalline phase produces a decrease of the refractive index. This phenomenon can be used to record phase volume holograms.

The maximum value of the refractive index modulation for PTRG is quite small (10^{-3}) compared to other holographic materials, but this is compensated by the very large material thickness and high transparency. Modulation times thickness ($\Delta n \cdot d$) in PTRG is enough to create very efficient volume hologram with diffraction efficiency exceeding 99%.

The photosensitivity of PTRG for 325 nm irradiation followed by 3 h of development at 520°C is about $1.5 \times 10^{-3} \text{ cm}^2 \text{ J}^{-1}$ which means that a standard exposure for high efficiency hologram recording is in the order of hundreds of mJ cm^{-2} . The spatial resolution of PTRG materials is particularly large ranging from 0 (continuous) up to $10,000 \text{ lp mm}^{-1}$.

Fig. 4 Production of embossed hologram from a photopolymer surface relief structure.

PTRG materials are particularly important because they are useful for manufacturing the fiber Bragg gratings that can be found in telecommunication fibers and fiber lasers. The fiber Bragg grating is used as a notch filter to select a particular bandwidth and reject all the others. Based on this principle, optical add-drop multiplexers can be built.

Another major advantage of the PTRG materials is their very high damage threshold. Being particularly transparent, they can withstand nanosecond pulses with an energy exceeding tens of mJ cm^{-1} (measured at 1064 nm, and 10 Hz repetition rate), and an average power exceeding 100 kW cm^{-2} of CW irradiation (measured at 1085 nm). This allows for creation of holographic beam combiners for high energy lasers.

For more information about photo-thermo-refractive glasses, see [Glebov \(2002\)](#).

Holographic Sensors

The spectral characteristic of the light diffracted by an hologram is extremely sensitive to the index modulation (Δn), and the spacing between the Bragg planes (Λ). This can be seen from the Bragg's [Eq. \(3\)](#) that can be further differentiated to find the spectral dispersion:

$$\frac{\Delta\lambda}{\lambda} = \frac{\Delta n}{n} + \frac{\Delta\Lambda}{\Lambda} + \cot\theta\Delta\theta \quad (4)$$

Therefore, if a recorded hologram is altered by its environment by swelling, or shrinking, the characteristics of the diffracted spectrum will change. This spectral, or color, change can be used as a sensor to detect the component responsible for the thickness change.

Gelatin emulsion, for example, is very well known to absorb the air humidity and swell. Swelling separate the Bragg planes already recorded and makes the hologram color shifts toward the red part of the spectrum, and eventually disappear in the IR. It is possible to then restore the original color of the hologram by dehydrating the gelatin by heating it up.

Based on this example of the gelatin, several other polymer matrices have been used to make the hologram sensitive to a wide variety of components. One can cite, poly(2-hydroxyethyl methacrylate) (pHEMA), poly(acrylamide) (paam), or poly(vinyl alcohol) (PVA), and poly(dimethylsiloxane) (PDMS). These matrices are porous to a selection of solvents, and their absorption will make them swell.

It is also possible to dope the porous polymer matrix with other molecules such as crown ethers that will bind with specific metal ions present in the solution and make the hologram sensitive to that specific ion.

Another example is the addition of 3-(acrylamido)phenylboronic acid (3-APB) into pAAm matrix. The 3-APB molecule can bound with glucose which makes the hologram a potential sensor for monitoring bodily fluid sugar.

This technique can be generalized to any chemical reagent sensitive to specific molecules. Once incorporated into the porous matrix that has been cross linked to form an hologram (see the case for the gelatin in Section Dichromated Gelatin), the spectral dispersion is affected by the presence of that particular molecules, and the hologram can be used as a sensor.

For more information about holographic sensors, see [Yetisen *et al.* \(2014\)](#).

Refreshable Materials

In this section we will introduce the holographic recording materials where the hologram can be erased, and the material reused to record a new diffraction pattern. This class of material is not used to permanently display the hologram, but rather, to present it momentarily, analyze the diffraction, change the recording setup, and write a new interference figure.

These refreshable materials can further be distinguished between those which are dynamic and do not need post processing for the hologram to appear, and those which need post processing. The advantage of the dynamic materials is that they do not need to be moved away from their original position in the recording setup before being read. This allows for a greater stability and reproducibility in the experiment, especially in holographic interferometry. The advantage of the non-dynamic material is that the hologram is more stable and will last longer even during the exposure by the reading beam.

Photochromic Materials

The word photochromism describes a material that changes its absorption coefficient due to illumination. This change of absorption can be used to record amplitude holograms. However, the diffraction efficiency of phase holograms is much larger, and the Kramer–Kronig relationship specifies that a change of absorption always goes along with a refractive index change, eventually at a shifted wavelength. So, it is better to use the photochromic material for its index modulation than its absorption modulation. To do so, the writing wavelength is tuned near the absorption peak, but the reading of the hologram is performed in a more transparent region of the spectrum, where the index modulation is enhanced.

The photochromic effect is a macroscopic, observable modification of the material property, and can be generated by many different microscopic alterations. It can be permanent: such as photobleaching; or reversible: like in photo-isomerization. Photochromism can happen in inorganic material, such as doped glass, or inorganic molecules, such as azoic dyes.

In photochromic glasses, the SiO_2 matrix is doped with a metallic compound such as silver halide crystals. Under light excitation, the transparent silver halide molecules undergo a decomposition into metallic silver particles, which are opaque. Because the halogen molecules are trapped inside the glass and cannot escape, they can recombine with the silver after the illumination is gone, and the glass retrieves its initial absorption profile.

Photochromic glasses are not often used for holography due to their slow response time and low sensitivity.

On the other hand, there exist several types of organic molecules that react to illumination by reversibly changing their absorption spectrum and refractive index. The most commonly used in optics and more specifically for holography recording are spiropyrans, diarylethenes, and azobenzenes. When a photon is absorbed by one of these molecules, it undergoes a conformation change such as isomerisation.

Some molecules such as bacteriorhodopsin have several metastable excitation states that can be addressed with different wavelengths. By taking advantage of this particularity, the hologram can be recorded at one wavelength, read non-destructively with another, and erased by a third. The selection of the different wavelengths is such that the recording is done in a strong absorption region of the molecule, the reading away from it in a transparent part of the spectrum, and the erasing excites the molecule into an unstable conformation that decays back into the stable form. This process is illustrated in [Fig. 5](#).

For more information about photochromic glasses, see [Glebov \(2002\)](#). For more information about photochromic organic molecules, see [Dürr and Bouas-Laurent \(2003\)](#).

Persistent Spectral Hole Burning

When cooled down at cryogenic temperature (liquid helium ≈ 4 K), photochromic materials can experience an inhomogeneous broadening of their absorption spectra. This means that each of the absorption centers (molecules or ions) acquire a narrow spectrum that is shifted in frequency due to the interaction with the host matrix (either glass or polymer). The material spectrum still spans a large bandwidth, but individual centers possess a narrow line as shown in [Fig. 6](#).

The observation of the inhomogeneous broadening requires very low temperature. This is because at room temperature the spectrum broadening of individual centers is due to the interaction with phonons and other excitation. At cryogenic temperature, these interactions are minimized, revealing the inhomogeneous broadening of the material.

If the host matrix was perfect at cryogenic temperature each absorption center would be in the exact same state, and the spectrum would be a single narrow line. In these conditions, no inhomogeneous broadening happens and no spectral hole burning would be possible. There will be only one spectral line.

The hole burning itself happens when the inhomogeneous broadened photochromic material is illuminated with a narrow bandwidth source such as a laser. The source will only excite the centers with a spectrum overlapping the light frequency. Once

Fig. 5 Molecular structures of the various isomeric forms of bacteriorhodopsin, and the different wavelengths used for writing, reading and erasing an hologram.

Fig. 6 Spectral broadenings. Top: at room temperature, the broadening is due to phonon interaction and the spectrum of individual center is large. Bottom left: at cryogenic temperature, in a perfect lattice, all the centers are in the same state and the spectrum of the material would be narrow. Bottom right: the spectrum of individual center is narrow but due to the interaction with the lattice each spectrum is shifted in frequency.

photo-excited, the molecule or ion composing the center will have a different absorption spectrum and leave a notch in the original absorption band as presented in Fig. 7.

An important parameter for spectral hole burning material is the ratio between the width of the notch that can be formed, Γ_{ZPL} (or zero phonon line), and the width of the material spectrum due to the inhomogeneous broadening, Γ_{inh} . This ratio indicates the number of individual frequencies that can be addressed in the material to record information, and can be as large as 10^6 .

Spectral hole burning materials can either be permanent or not. It is reversible if the photo-excited state of the absorption centers can decay back to the original state. The temporal behavior is strongly dependent on the material, the temperature, as well as the mechanisms of relaxation that bring back the excited state to its original state. Hours of dark decay time have been demonstrated.

The interest of spectral hole burning for holography comes from the possibility to use massive wavelength multiplexing. Each individual spectral notch that can be created is an opportunity to write a different and independent hologram. The use of the frequency domain to record the hologram is a new dimension for encoding the information in addition of time and space, which increases dramatically the quantity of information that can be stored in the material. Spectral hole burning gives the opportunity to increase the capacity of holographic data storage, and can also be used to design very high density correlation filters.

For more information about persistent spectral hole burning and its application for holography, see Moerner (1988).

Polarization Sensitive Materials

Some of the photochromic materials are sensitive to the light polarization and can be used to record not only amplitude-modulation holograms but also polarization-modulation holograms. This mechanism is also referred to as orientational hole burning in comparison to spectral hole burning.

Polarization holograms are formed when two coherent beams with orthogonal polarization interfere. In that case, the intensity is constant but the polarization vector changes along the period of the grating. For left and right circular polarized recording beams, the modulation is a linear polarized vector whose direction is rotating around the bisector of the beams propagation. For linear s- and p-polarized recording beams, the modulation is elliptical polarizations changing direction. These cases are presented in Fig. 8.

Sensitivity of photochromic molecules to polarization can be explained by the preferential absorption when the electric field is aligned to the axis of delocalized electronic orbital. This is the case of the azobenzene dyes that become oriented perpendicular to the light electric vector after multiple trans-cis photoisomerization and cis-trans relaxation cycles. During each cycle, the molecule

Fig. 7 Spectral hole burning principle: a narrow band source only excites the centers that have a spectrum overlapping the source frequency. The center excited states have a different spectrum which leave a notch in the material initial spectrum at the same frequency as the source.

Fig. 8 Polarization gratings formed by the interference of, left: left and right circular polarized coherent beam. Right: s- and p- polarized coherent beams.

can rotate by a finite and random amount. Over a large number of excitation-relaxation cycles, the molecule distribution becomes predominantly organized with the main axes orthogonal to the polarization. The orientation is a statistical process and is not driven by any torque, which means that it is rather inefficient, explaining the slow dynamic time of the material in comparison to the very fast isomerization process.

In some materials, the multiple transitions also induce a molecular migration that can leave a surface relief modulation in addition to the volume phase hologram.

Even though the *trans*- and *cis*- forms of the azobenzene have different absorption spectra, the photo-orientation process leaves the molecules in their relaxed form (*trans*). The hologram formed in this case is a phase modulation due to the birefringence induced by the anisotropic molecular distribution.

Sensitivity of polarization sensitive azobenzene is on the order of mJ cm^{-2} , and the index modulation achievable is rather large, on the order of 10^{-2} .

For more information on polarization holography and polarization sensitive materials, see [Nikolova and Ramanujam \(2009\)](#).

Photorefractive Materials

The literal meaning of a photorefractive material is one that changes its refractive index under illumination. However, the scientific community has come to define the photorefractive process very specifically as the reversible and dynamic change of the index due to an electronic process. So, photorefractive materials should not be confused with photochromic even though the observable macroscopic effect is similar.

The photorefractive effect is a multiple step process that starts with the absorption of photons and the generation of electric charges inside the material. This aspect is similar to the photovoltaic process. Both electron and hole charges are created since there is conservation of the material electrical neutrality. However, in photorefractive materials, the mobility of the charge carrier depends on its sign. One type of charge carriers migrate inside the material while the other type stays in the localization where it was created. There are several charge transport mechanisms such as diffusion, drift (under external electric field), and photovoltaic that explain this migration. The mobile charge carriers are eventually trapped in the dark regions of the material, and the local charge distribution creates a space-charge electric field between the illuminated and dark regions of the material. This space-charge field modulates the index of refraction by either nonlinear electro-optic effect (in inorganic crystals) or molecular orientation (in organic materials).

The different steps leading to the photorefractive process is presented in [Fig. 9](#).

The photorefractive effect is characterized by a phase shift (φ) between the intensity pattern and the index modulation. This phase shift is responsible for the self-diffraction of the recording beams in a two beam coupling experiment.

Photorefractive materials can be organized into two different categories: inorganic crystals and organic compounds. Inorganic crystals are grown at high temperature and their composition is imposed by their stoichiometry and crystalline structure. Some inorganic dopants, such as metallic atoms, can be incorporated to modify the electro-optical properties like absorption band or carrier mobility. Examples of inorganic crystals include the silenites ($\text{Bi}_{12}\text{SiO}_{20}$, $\text{Bi}_{12}\text{GeO}_{20}$), strontium-barium niobate ($\text{Sr}_x\text{Ba}_{1-x}\text{Nb}_2\text{O}_6$), barium titanate (BaTiO_3), lithium niobate (LiNbO_3), as well as semiconductors such as GaAs, InP, and CdTe.

Photorefractive organic compounds are mixtures of several organic molecules exhibiting specific function to achieve the photorefractive effect. They are mainly composed of a photoconductive polymer matrix that allows the charge transport. Such matrices are PVK: poly (N-vinylcarbazole), or PATPD: poly (acrylic tetraphenyldiaminobiphenol). To enhance the sensitivity in the

Fig. 9 Photorefractive process starting with the intensity distribution of the interference pattern, charge photo-generation, charge transport and distribution after migration and trapping, space-charge field, and final index modulation.

visible the matrix is doped with a sensitizer that is responsible for the charge photogeneration. The most used sensitizer that covers a large band in the visible region is a derivative of the C_{60} fullerene molecule, PCBM: phenyl-C61-butiric acid methyl ester. The index modulation is provided by chromophores, rod-like molecules with large dipolar moment and polarizability, such as DMNPAA: 2,5-dimethyl-4-nitrophenylazoanisole, or 7-DCST: 4-azacycloheptylbenzylidene-malonitrile. To increase the mobility of the chromophores that need to orient in the space-charge field, the glass transition of the polymer matrix is lowered with plasticizers, low molecular weight molecules such as ECZ: N-ethylcarbazole, or BBP: n-butyl benzyl phthalate.

The optical properties of the photorefractive crystals and organics are strongly dependent on their nature and cannot be generalized. Their sensitivity ranges from $\mu\text{J cm}^{-2}$ to mJ cm^{-2} , and their spectral response varies through all the visible up to the infrared.

Due to their very specific properties, photorefractive materials are used in numerous applications, such as phase conjugation, coherent beam amplification, imaging through turbid or scattering media, dynamic holographic imaging, and holographic interferometry.

For more information on photorefractive inorganic crystals, see [Günter and Huignard \(2007\)](#). For more information on photorefractive organic materials, see [Blanche \(2016\)](#).

Photo Thermoplastic Process

The term Photo Thermoplastic does not describe a material, but a material process. Thermoplastic polymers have their structural rigidity altered by temperature. By heating a sheet of material it becomes supple and can be deformed. This property can be exploited to record a surface relief hologram which is encoded in the deformation of the surface of the sheet. To do so, the thermoplastic material is coated on the top of a photoconductor. The surface of the photoconductor is charged by corona discharge which attracts opposite charge on the top of the thermoplastic. When illuminated, the charges that were on the top of the photoconductor migrate through the material and came in contact with the thermoplastic. After illumination, the photoconductor is charged a second time. Because of this second charging, there is now more charge in the region that was illuminated than where the material was not exposed to light. At that moment, the thermoplastic material is heated up and the electrostatic attraction between the charges squeeze the film, modulating its thickness. To erase the surface relief, the material is evenly charged and heated. These processes are illustrated in [Fig. 10](#).

For more information about the photo thermoplastic process, see [Lin and Beauchamp \(1970\)](#).

Electronic Devices

Twenty years ago, there was a technological transition from analog to digital photography. This transition was possible thanks to the development of the focal plan array detector and the personal printer. Today, we are assisting to the same kind of transformation for holography. More and more often, the analog recording media is substituted for an electronic device. This transformation is made possible by the high resolution of both the detectors and the micro display devices. Once again, when photography requires micrometer resolution, holography, which records the wavefront features, requires nanometer precision. Needless to say, this is much more difficult to achieve.

The advantages of the electronic devices are numerous. They are dynamic and do not require post processing to capture the hologram, they can be used over a very large wavelength bandwidth, they allow computer manipulation of the holographic pattern for direct interpretation or eventual transformation, they are easy to use, and they are reusable with no pre-processing.

The figure of merit for the recording and reproduction of holograms by electronic devices is the space-bandwidth product (SBP), which is a measure of the rendering capacity of an optical system. It is defined as the product of the spatial frequency bandwidth and the spatial extent of the image. In other words, at constant SBP you can either capture/reproduce a small image at high resolution, or a large image at low resolution. The transformation from one to another can simply be performed by a magnifying lens.

Although very useful and convenient, electronic devices are still suffering from a coarse resolution and pixel count compared to the recording materials (small SBP), but this might be solved in the very near future. A more fundamental problem is their inability to record and reproduce volume holograms. Detectors only record the interference along a plane, and the current micro-

Fig. 10 The photo thermoplastic process: charging the material, exposure drives the charges inside the photopolymer, the second charging increases the electrostatic attraction where the material has been exposed, heating the thermoplastic modulates the surface relief.

displays only produce surface relief modulation. For a volume hologram to be recorded, the phase needs to be sensed over a non-negligible thickness, and reproduced likewise. This excludes both the sensing and reproduction of reflection hologram by electronic devices.

Even with these limitations, electronic devices are used in a large variety of holographic setups, from 3D display to microscopy and adaptive optics. They are promising the same bright future for holography as the one they created for photography.

Focal Plane Array Detector

The function of detecting the intensity modulation generated by the interference of the coherent beams is provided by the focal plane array detector (FPAD). Two technologies can be used: either charge-coupled devices (CCDs), or complementary metal-oxide-semiconductors (CMOSs).

These devices have been popularized by digital photography and are very well known, even outside the scientific community. It is only recently, however, that the pixel pitch and count made them interesting for holography. A commercial grade FPAD can now have 20 million pixels with a 4-micron square size. This size of pixel correspond to a resolution of 125 lp mm^{-1} which is far from the several thousand that analog materials offer, but is enough for detecting interference fringes for in-line holography, or low angular separation beams at long wavelength.

Scientific grade FPAD can have a pixel size down to 2.2 μm for a total of approximately 120 million pixels on a single sensor. The problem with decreasing the pixel size is the same as with the silver halide emulsion: when the size shrink, there are fewer and fewer photons interacting with the pixel (crystal), and the sensitivity decreases dramatically. This is particularly true for the CMOS technology where the pixel surface is shared between the sensing area and the electronic amplification and logic.

Once the interference pattern has been detected by the FPGA, it can be used to reconstruct the 3D light field (phase and amplitude) using a computer, or displayed by another electronic device to reproduce the hologram.

For more information about the use of focal plane array detector for holography, see Schnars and Jüptner (2002).

Acousto-Optic Modulator

A sound wave is a compression wave propagating inside a material. This compression (and dilatation) modulates the index of refraction and if the frequency is carefully selected, can be used to diffract the light. Acousto-optic modulators (AOM), use this principle to generate diffraction gratings. They are composed of a piezo-electric transducer (PZT) that generates the wave, which is coupled to a transparent medium, generally glass, quartz, or other crystal. Two configurations are presented in Fig. 11. The first one is the commonly used Bragg cell, where the sound wave generated by the transducer travels inside the material. The second is one where the transducer is put on top of a waveguide and generates a surface acoustic wave. The wave diffracts the light out of the waveguide so this configuration is called leaky-mode coupling.

There are two modes of operation for the Bragg cell: static and traveling wave. When the acoustic wave is traveling, it shifts the diffracted beam frequency due to the Doppler effect. This shift is about 1 GHz due to the speed of sound in the material. To avoid this shift, a sound reflector can be used at the other end of the material. This reflection generates a standing wave like in musical wind instruments.

By changing the frequency and the amplitude of the vibration at the PZT, it is possible to change the diffraction angle and amplitude. AOM can achieve a diffraction efficiency up to 99%.

The sound wave can only generate diffraction gratings that redirect the incident beam but do not change its wave front. Used simply as is, AOMs would not be able to form a 3D image. However, if instead of using a fixed frequency, the AOM is driven with a sum of many frequencies, it becomes similar to a one-dimensional arbitrary holographic pattern: any waveform can be decomposed as a sum of sinusoids.

The advantage of the AOMs is their very large space-bandwidth product compared to the spatial light modulator. An AOM can produce larger images size, and larger view angle than the other technologies.

Fig. 11 OAM configurations. Left: Bragg cell where the sound wave generated by the transducer modulates the index inside the material. Right: leaky-mode mode coupling where the transducer produces a surface acoustic wave on top of a waveguide.

Due to the very fast reaction time, AOM are driven by a signal ranging from tens to hundreds of MHz. AOMs are used for Q-switching pulsed lasers, for pulse shaping, in telecommunication to modulate the optical signal so it carries the information, and in spectroscopy for frequency control.

For more information about acousto-optic modulator, see [Efron \(1994\)](#).

Spatial Light Modulator

Spatial Light Modulators (SLM) are dynamic pixelated electronic devices where each pixel can be individually controlled to change the amplitude or the phase of an incoming light beam. Initially developed for the display industry, SLMs are also called micro displays because of the small size of the pixels. Thanks to that small size, they can also be used to display holographic patterns, which diffract the incident visible light over an appreciable angle. Larger pixels reduce the angle of diffraction according to the Bragg equation and need to be used at larger wavelengths.

Micro displays where the light is directly emitted from the pixels such as in light emitting diodes (LEDs) and thin film transistors (TFTs), cannot be used for holography since the phase of the different sources cannot be controlled individually. A micro display system where the phase of the light emitter could be controlled would be the equivalent of a phase array radar for the visible and is currently the object of active research.

Because SLMs are dynamic and refreshable at will, they are extremely attractive for dynamic holography applications such as optical tweezers, optical switching, non-mechanical scanner, wave front correction, and holographic interferometry.

Of course, 3D display is also a potential application, but the space-bandwidth product of commercially available SLMs (number of pixels over the pitch) is still too small to generate a comfortable 3D image, even with a 4 K UHD resolution: 4096×2160 pixels. Systems tiling several SLMs together to increase the SBP have been demonstrated though.

Two types of SLMs can be distinguished according to their mode of operation: liquid crystal on silicon (LCoS) and micro-opto-electro-mechanical systems (MOEMS).

Liquid crystal on silicon

Liquid crystals (LCs) are liquid form materials composed of birefringent molecules that self-align. Due to their large dipole moment, the LC molecules are also sensitive to externally applied electric field. When an electric field is applied the molecules rotate, which changes the optical properties of the material: birefringence amplitude and axis, as well as the refractive index.

In LCoS SLMs, a layer of LC is deposited on top of a complementary metal-oxide-semiconductor (CMOS) structure forming individual cells where the voltage can be applied independently. This is the same technology used in liquid crystal display (LCD) and LC television. When a voltage is applied, the LCs induce phase retardation in the polarized incident light as large as a few wavelengths, which is enough to produce a fully modulated (2π) holographic phase pattern. This phase modulation can take multiple values (usually 8 bits = 256 levels), which allow the LCoS to reproduce continuous phase holograms.

It has to be noted that at maximum spatial frequency, the pattern is only represented by 2 pixels per period, and only binary phase can be displayed. To reproduce multilevel functions, several pixels need to be used and the frequency is reduced.

To increase the reflectivity of the device, a layer of aluminum or dielectric mirror is coated between the LC and the CMOS electronic. The mirror can be ordered according to the wavelength at which the device is supposed to be used (IR, visible, or specific laser line) which give a reflectivity larger than 90%.

Amplitude modulation LCoS displays use a polarizer in front of the SLM so the phase retardation is converted into amplitude modulation following Malus's law: $I = I_0 \cos^2 \rho$, where ρ is the angle between the polarization vector and polarizer direction. This mode of operation is not interesting for holography since amplitude holograms only reach 10% in the first order.

A phase only LCoS is more interesting for holography due to the higher diffraction efficiency (up to 100%). In this case, the device modulates the index of refraction directly, according to the main axes of the birefringence.

Typical LCoS pixel pitch is a few microns, which offers a maximum diffraction angle of a few degrees in the visible (4 mm pitch $\approx 4^\circ$ in the visible). The pitch is limited by the field bleeding from one cell to another and it would be hard to reduce it further in the future. An LCoS benefits from a fill factor (active pixel area over pixel size) as large as 90%. The refresh rate is limited by the viscoelastic relaxation of the molecules but can increase up to a few hundred Hz. Unfortunately, this refresh rate does not allow for the time multiplexing or very fast reconfiguration sought in some holographic applications.

For more information about LCoS SLM and holographic application, see [Osten and Reingand \(2012\)](#).

Micro-opto-electro-mechanical systems

Micro-electro-mechanical systems (MEMSs) are devices where a micron scale mechanical feature can be activated by an applied voltage. When this device is also used to interact with light, it is named MOEMS with the introduction of the term "opto".

The best known of these MOEMSs, due to its commercial success, is the Texas Instruments DMD (digital micromirror device) which is also known as the DLP (digital light processor). The DMD is used in display applications such as televisions and projectors. It is composed of an array of micron size mirrors: $13 \mu\text{m}$ for the $0.7''$ XGA, down to $5.4 \mu\text{m}$ for the 1080p "pico". The size of the DMD follows the resolution standard for display: XGA = 1024×768 , 1080p = 1920×1080 , WQXGA = 2560×1600 .

The DMD is a binary device and the mirrors can only take two orientations: tilted left or right by 12° for the large DMD, or 17° for the pico, according to the surface normal. Accordingly, the DMD can be used to display binary amplitude holograms. The incident light is reflected by the mirrors, and since the pattern is composed of left and right tilted mirrors there are two reflection

Fig. 12 Geometry of diffraction from the DMD.

directions θ_r (or zero orders). In each of these directions, there are multiple diffraction orders ($\pm 1, \pm 2, \dots$) due to the diffraction by the structure created by the mirror orientation (see Fig. 12). The maximum angle of diffraction (θ_d) around the 0 orders is given by the pixel pitch and is about 2° for $13 \mu\text{m}$.

The maximum diffraction efficiency for the binary amplitude hologram displayed by the DMD is 10.1% as predicted by the Fourier decomposition theory. However, the big advantage of the DMD is its refreshing rate, which can be up to 20 kHz (100 times faster than LCoS). This enables applications that are not accessible with LCoS SLMs.

That fast refresh rate is what allows the DMD to display numerous intensity levels (10 bit gray scale), although it is a binary device that can only display black (light reflected away from viewer) or white (light reflected toward viewer). By oscillating the mirror at different frequencies, the intensity directed to the viewer is modulated. This only works because the eye integration time is rather slow ($\approx 24 \text{ Hz}$) compared to the 20 kHz of the device. DMDs cannot be used for applications requiring smaller integration time.

Another diffractive MOEMS worth mentioning is the grating light valve (GLV) which is composed of parallel thin ribbons (few micron pitch) that can take two positions: up or down. The phase difference generated by these two positions can be used to diffract the incident light with 40% efficiency (binary phase hologram). The GLV has been shown to have a refresh rate of up to 50 GHz (2000 times faster than the DMD), but also has some severe limitations for holography: it is a 1-dimensional array and only 1 or 2 ribbons can be activated at a time.

Other types of MOEMS are under development specifically for holography. One such device is an analog piston MOEMS where the micro-mirrors are moved up or down according to the voltage applied. Like in the GLV, this movement creates a phase difference between the mirrors which diffracts the light. The difference from the GLV is that the mirrors can be positioned at multiple levels instead of just two. This allows users to display a continuous phase hologram which can have a diffraction efficiency as high as 100%. Such a piston MOEMS will combine both the efficiency of the LCoS, and the speed of the DMD. If a piston MOEMS can be manufactured with a very large number of mirrors (hundreds of trillions), it could enable true holographic television along with other diffractive applications.

For more information about MOEMS SLM and holographic application, see [Blanche et al. \(2015\)](#) as well as [Blanche et al. \(2017\)](#).

Colour Holography: Perception Versus Technical Reality

Andrew Pepper, Nottingham Trent University, Nottingham, United Kingdom

© 2018 Elsevier Ltd. All rights reserved.

The opportunity for optical holography to record and display three-dimensional objects (and the volume surrounding them), at extremely high fidelity, has prompted a distorted public perception. Almost since we became aware of the process, and its capabilities, there has been an assumption that the remarkable dimensional images would be in full (natural) colour. This is not a surprising supposition due to the clarity and illusionistic impact of holographic images displaying full parallax (Benton, 1977). Our familiarity with looking into display spaces, very much like looking through a window into a room in a building (Pepper, 2000), suggests that what we appear to 'see' must surely be in full colour.

Most of the first holograms produced were monochromatic; a limitation of the technical processes which created them. When Dennis Gabor first published the announcement about his work with optical holograms in 1947 (Gabor, 1948), he used a heavily filtered mercury arc lamp to record and illuminate his photographic plates, which stored the microscopic interference patterns on which holograms rely. This was the only suitable and accessible source of light at the time, which fit the specific requirements of his optical recording configuration, but it did limit the size of the object he could record to a few millimetres.

These early holograms used Gabor's 'in-line' recording process, which placed the 'object' to be recorded directly between his chosen source of light and the photographic plate. Light waves, directly from the illuminating source, and those modulated through diffraction by the object, were combined on the photographic plate to record the resulting, microscopic, interference wave pattern.

The reference to an 'object' here is intentionally placed in inverted commas as Gabor used a flat photographic transparency for his recording. Although the transparency is physically three-dimensional, and millimetres thick, there is a tendency to describe it as flat because of our learned visual, perceptual and verbal framework used to view and describe 3-D. This aspect of these early recordings, and the demonstration of the optical and physical viability of this new method for recording three-dimensional objects caused a slight perceptual and cultural friction. If it is three-dimensional, it is likely to be incredibly accurate, and if it is so accurate, it is reasonable to assume that it is correctly coloured. Feedback from visitors to exhibitions of optical holography includes incorrect assumptions that some of the monochromatic images they have encountered are, when recalled and discussed, full colour. We have a natural tendency to 'fill in the gaps', and this is incredibly easy to do when confronted with the astounding three-dimensional illusion of a holographic image.

The tendency to make such an incorrect assumption is not an isolated phenomenon. Evidence through teaching fine art to undergraduate students suggests that they encounter much of the art they look at (or explore for research) online. They view multiple images of the same work, made up of gallery installation shots, close-up details and peripherally photographed views, which are scattered across the web or in printed catalogues, and often believe they have 'seen' the original. It is only when they then encounter the actual work that they realise they have not seen the work, only its documentation.

A major shift in public perception of holography was directly related to two significant developments of the technical process in the United States and USSR. Emmett Leith and Juris Upatnieks developed an off-axis geometry, which used coherent, monochromatic, laser light, to record and display holograms. This more powerful, coherent, light source, and the optical pathway they developed, allowed the recording of 'actual' three-dimensional objects (rather than Gabor's 'flat' transparencies).

The results of their research were disseminated to the scientific community (Leith and Upatnieks, 1962) but an article in the widely circulated magazine 'Scientific American' (Leith and Upatnieks, 1965) brought it to the attention of a wider audience, interested in broad scientific topics. Culturally this was a positive, future-looking, period with an enthusiastic public awareness of new technologies stimulated by the space race and rapid scientific advances. This publication informed a different demographic beyond the technical papers previously published in field-specific scientific conferences and journals. Unsurprisingly, the 'improvement' on Gabor's original invention, and its implied connection with photography (in the title of the article and through the text), captured the public view and that of popular media. Generalised information about optical holography spread quickly, with many popular articles appearing worldwide (Johnston, 2006). Subsequently, public interest and expectations about holography increased, which fuelled many inaccuracies - one of the main ones being that holograms were full-colour.

This public confusion about the realistic nature of holograms was evident during the late 1970s when two important exhibitions of large-scale pulsed laser holograms, produced by Nick Phillips (1933–2009) at the Royal Academy of Arts, London, proved extremely successful and not only attracted the attention of an 'art' sensitive public, visiting a renowned institute, but also that of the media. Some of the reports and images disseminated around this time blurred the line between what was possible with the technique and high public expectation. It was difficult to be sure whether the images from these exhibitions, reproduced in glossy colour supplements, might be full colour.

Leith and Upatnieks did propose colour holographic recording as early as 1964 (Leith and Upatnieks, 1964), but there was a need for the technical components to become available and accessible, mainly multiple colour, coherent, laser light and high-resolution recording materials.

During the same period, Yuri Denisyuk demonstrated significant developments, which also used an off-axis system of recording and display (Denisyuk, 1962). This incorporated a single beam of coherent laser light which passed through the holographic recording plate, bathed a three-dimensional object in laser light, and the subsequently reflected light from that object was combined with the laser light shining through the plate, to generate the required microscopic interference pattern. The advantage

of this 'single beam' technique (not to be confused with Gabor's in-line method) is that the resulting hologram could be displayed using white light. This significant development played an important part in the adoption of holography as a display (and archival process). All previous systems required expensive, and potentially dangerous, mercury arc (Gabor) or laser (Leith and Upatnieks) light. Here, inexpensive white lights, such as spotlights or direct sunlight, could be used to reconstruct the recorded three-dimensional images.

A drawback to Denisyuk's technique was that objects needed to be relatively shallow, compared to the amount of volume which was possible to record in Leith and Upatniek's technique. It appears the more accessible, English language, publications about Leith and Upatniek's activities placed them prominently in the public eye and that of the US and European media outlets. It is also worth noting that the term 'hologram' was not in common use before the mid-1960s, with terminologies such as wavefront reconstruction, diffraction microscopy, Gaboroscopy, holoscopy, wave photography and lensless photography, appearing in publications (Johnston, 2009).

The various techniques and optical processes were, theoretically, capable of recording full-colour holograms. As early as 1966, Lin and his team successfully produced the first full-colour reflection hologram, which used two different wavelengths of light, recorded and combined onto a single holographic plate (Lin *et al.*, 1966). This was, in fact, a recording of a colour photographic slide, which we might interpret as 'flat' but, like Gabor's original work, it demonstrated the feasibility of using multiple wavelengths (colours) of light which, combined, will produce the impression of full colour.

Red, Green, Blue

Most of the early holograms recorded, irrespective of the optical technique employed, used a monochromatic light source to record and display a three-dimensional object. As previously stated, the optical illusion and impact of the recorded images were so significant that the 'memory' and recall of seeing these holograms often prompted a distorted perception among viewers, thinking they had 'seen' the images in full colour.

An image recorded with red, helium-neon, laser light, for example, will display a tonal red, three-dimensional image, when displayed using the same red laser light. There will be no other colours present. Much of the early research on colour holography used the principle that it would be possible to use multiple colour lasers to record a hologram and then use the same lasers to display the results.

As white light is made up of multiple colours (wavelengths), using the light primary colours of red, green and blue will allow the recording and reconstruction of a full-colour image. This phenomenon of colour reproduction is based on the tristimulus theory of colour vision, which suggests that any colour can be reproduced (or matched) by combining the three light primary colours.

It is possible, therefore, to make a holographic recording using red laser light (helium-neon), then make a second exposure using green laser light (argon) and finally a third using blue laser light (helium-cadmium). The colour of a laser can vary, depending on the gases/materials used within the device to cause the light amplification process. This can include krypton ion (red), neodymium-doped yttrium aluminium garnet (green) and argon ion (blue).

Once processed, the developed hologram can then be illuminated with these three colours of laser light. In effect, each of the three-dimensional recordings in the hologram 'overlap' and then combine, spatially, to reconstruct the colours of the original object in their original position in space.

Three objects are presented, which overlap each other in space and combine to create a single, full-colour object/image. This is a unique property of holography, and one of the few opportunities to place visually solid, three-dimensional images of objects into the same space at the same time. Such 'overlapping' has always been possible with multiple exposure photography and use of multiple camera feeds in video, but only holography allows this in full parallax, full three dimensions.

During the 1970s, there was a considerable amount of research in the field of colour holographic recording, which took advantage of the technical improvement in light sources, recording materials and optical components (Hariharan, 1983).

Although the cost of lasers has dropped and their quality (and variety) improved, they remain complex, and in some cases fragile or dangerous (depending on their power and wavelength). This has limited their use in display. Clearly, the option of recording holograms with multiple colour laser light and then viewing them with white light is a practical solution, and a considerable amount of research has been undertaken, using reflection holography (often employing the Denisyuk process) with a significant pioneering research by Bjelkhagen (2006).

Research suggests that the optical quality and colour rendition of holographic displays can be enhanced using multiple wavelengths of laser light and more than three colour recordings (Mirlis *et al.*, 2005). The reproduction of colour has become accurate enough for it to be viable as an archival system for paintings, which can be captured using a contact recording technique, this not only accurately records the colours within the painting, but also the three-dimensional undulations of the painting surface. Each brush stroke, its thickness, and texture of the paint, is stored and can later be displayed (Bjelkhagen and Vukicevic, 2002). As an archival process, this has considerable potential – extending the visibility of paintings, which now have a restricted display life due to potential light damage. Maintaining their colour is a significant requirement of the preservation process even if, in this case, it is shown in a high-resolution facsimile.

One holographic technique, invented by Stephen Benton (1941–2003) in 1968 (Benton, 1969), impacted on the production of colour holography significantly and was extremely popular within the display, advertising and creative arts industries during the 1970–90s. This two-step process used a laser transmission hologram of a three-dimensional object, which was then 'copied', or rerecorded, onto a second holographic plate through a restricted optical 'slit', with the resulting

hologram being displayed using inexpensive white light. The optical and practical 'trade-off' here was that the display hologram produced a three-dimensional, full-parallax, image when an observer moved from left to right (or right to left) in front of the display. This allowed the observer to look 'round' objects in the hologram offering shifting points of view, as you would expect when looking at a scene through a window. You can, for example, move your point of view and look behind a three-dimensional object in the foreground so that you can see a hidden, three-dimensional object in the background, much like we do in real life. The reason why this type of hologram is of interest in connection with colour holography is that the optical production and reconstruction of this kind of hologram produces a rainbow-colour effect, which 'covers' the displayed image. These are often referred to as rainbow holograms or white-light transmission holograms.

Although parallax exists when moving left to right – when an observer moves up and down, the parallax view remains the same (so the images 'freezes') but also changes colour from red, through green, to blue. Its apparent size can also appear to shrink or expand. Although this limit in parallax viewing and shift in colour is a side effect of the production process, it presented commercial and visual advantages. The technique allowed printed mass production of holograms and prompted a surge in their use on credit cards, publications, textiles, manufacturing plastics, novelty gifts and commercial products.

Pseudo Colour and the Manipulative Artist

Benton's technique is often described as pseudo colour holography because the colours on show have no direct connection to the actual colour of the three-dimensional object which was initially recorded. This term can be applied to any hologram which produces a similar effect and covers both white-light reflection and transmission techniques. A US patent was granted for pseudo colour holography in 1991.

Pseudo colour holographic display was incorporated into a number of different systems, including the separation of two-dimensional graphic images, which could be combined (overlapped) to produce full-colour images. This had considerable impact on mass-produced commercial printing and novelty gift production (McGrew, 1982).

Although this 'inaccurate' or sometimes 'unfixed' colouration within pseudo colour holograms is viewed as a disadvantage to precise reproduction of objects, it is acknowledged by artists and designers as a flexible and creative, spatial, colour technique. Benton understood this and supported many artists in the use of his technique, offering master classes as well as accessible conference publications. A number of key artists adopted this technique (or a variety of it) and tested it to its visual and technical limits, allowing them to 'manufacture' or 'capture' light, change its colour and use it as a sculptural material in space. Artist Rudie Berkhout (1946–2008) is acknowledged as a pioneer in this field, and his colour holograms are in significant public and private collections worldwide. One aspect of the use and development of holographic colour by artists is that they are unbridled from the specific requirements of industry, results-driven, exploration. Where most optical scientists work on a particular problem which requires a quantifiable solution, often set externally by a funding agency or commercial consultation, artists set their own boundaries to develop skills and techniques relevant to their practice. Berkhout used innovative and practical solutions for recording and displaying colours in his work, which might be considered an unlikely requirement, or aberration, in an optics research programme. He was able to create and manipulate three-dimensional objects and images, which were not recorded from a corresponding (recognisable) object, and as his career progressed, this exploration became more abstract and confident.

Berkhout's work has a visual vocabulary developed over many years, and several other artists have used the technical opportunity to display 'pieces' of light and colour within space. A line, shape, mark or word can be presented, unsupported in space, using holographic colour recording techniques. Early works by artist Eduardo Kac displayed 'floating' and overlapped letters and words which made up his series of Holopoems, produced between 1983 and 1993. Unlike Berkhout, they are grounded through the use of text, which can be viewed from multiple angles, as an observer moves around the hologram, offering spatial fluidity and semantic interpolation. There are a large number of pioneering artists who produced exceptional works with colour and their contributions to the visual arts can be found in numerous exhibitions, catalogues, public and private collections.

Another pioneer in the field, artist John Kaufman, used the often unwanted side effect of reflection holography, namely the swelling of the recording emulsion, which results in a colour shift when the hologram is processed and displayed.

The majority of holograms are recorded onto a high-resolution photographic emulsion, which is then wet-processed in chemicals (similar to those used in the development of photographs). Submersion in these chemicals, and wash baths, causes the exposed photographic emulsion to swell. Once dry, the emulsion returns to its original volume/thickness (or very close to it). In white-light reflection holograms, this is an essential element in their production and processing. During display with white light, the processed emulsion absorbs unwanted wavelengths of light and then reflects the wavelength (colour) of light used in the recording. If a red laser is used to record the hologram, the thickness of the processed emulsion should cause only red light to be reflected, and the resulting holographic image would appear red. Occasionally, the processing of the hologram, or inconsistent drying of the emulsion after wet processing, can cause the emulsion to dry to a different thickness. This will change the wavelength of light absorbed and reflected during reconstruction of the hologram and subsequently change its apparent colour.

Artists and display companies have used this to their advantage, and there was a period in the 1980s when reflection holograms for commercial and archival display used emulsion which was intentionally swelled so that the resulting image would appear yellow gold, rather than the original colour of the laser used to record it.

Kaufman developed a technique using chemicals to pre-swell the emulsion on the holographic plate, record a three-dimensional object and, before processing, re-swell the emulsion to a different thickness, record another object, and often repeat

this several times until finally chemically processing the hologram. What resulted was an emulsion which dried to slightly different thicknesses and, when illuminated with white light, would absorb and reflect a variety of wavelengths in the various regions of the holographic plate. The viewer of these works would see fully three-dimensional, full-parallax, images in different colours within the recorded holographic space. This is a controlled system with long production times and a very high degree of uncertainty, as the resulting image is only visible once all the swelling, recording and processing is complete. It is not possible to return to a particular stage of the process and change it – the entire hologram would need to be remade. This limited the use of this process commercially, but enhanced its use in limited, or unique, editions by artists.

Other artists have used a less prescriptive method of emulsion swelling, which subsequently produces a more abstract spatial result. This includes swelling small parts of the emulsion across the surface of the holographic plate without predefining the result. Some artists have used their body surface as a tool for application of swelling agents onto the surface, others incorporate brushes, fine drawing devices or specially cut templates to define and contain the area of swelling. The process functions much like mark-making or the application of paint on a surface but, in this case, the area being manipulated with colour is spatial and volumetric – drawing and colouring in space.

Colour generation and ‘shifting’ is not limited to emulsion swelling. Several artists exploited the rainbow effect within white-light transmission holography, particularly the production and manipulation of holographic optical elements (HOEs). Already a successful process for generating optical elements with extremely specific characteristics for photonic research and development, they are also used by artists as a method of capturing, structuring and manipulating white light to explore the liminal spaces these constructions can produce. Fred Unterseher, one of the pioneers in this technique, and a significant artist/teacher of accessible holography, commented that; “The virtue of a holography class and the holography experience is to transform the way you see, to transform the way you experience; the value of this is to see light and to experience (it) in new ways...” (Johnston, 2006).

As the techniques and technology of holography have developed, there are now a number of commercial companies and research facilities which offer accurate full-colour analogue and digital holographic recording. This has clear commercial impact in military reconnaissance, advertising, architecture, visualisation and museum archiving. Subsequent adoption in this area should stimulate the industry and its competition with illusionistic computer graphics or virtual reality. The undeniable advantage of colour holography continues to be its ability to record and display extremely high-resolution objects in full parallax three dimensions without the need for a viewing device. Where this, perhaps, differentiates itself from developing display technologies is its perceived state of hyper-reality, evidenced by the recent significant advances in ultra-realistic holographic imaging techniques (Bjelkhagen and Brotherton-Ratcliffe, 2016) The ability to specify colours in space can allow significant applications in spatial ‘signalling’ or object differentiation, while artists have a physical and conceptual opportunity to explore and manipulate colour in ‘real’ three dimensions.

What began with Gabor in 1947 as an attempt to improve the resolution of the electron microscope has partly developed into a new technical and creative vocabulary for colouring our spatial environment.

High-Resolution Underwater Holographic Imaging

John Watson, University of Aberdeen, Aberdeen, United Kingdom

Introduction

Holography is well-known to most of us: many will have seen white-light display holograms in exhibitions, shops and on credit cards. The word “hologram” has passed into general usage and has come to be associated, somewhat erroneously, with any three-dimensional or pseudo-3D image regardless of how it was formed. The impact and influence of true holography, however, spreads far and wide beyond display and entertainment confines and into the whole spectrum of science, engineering, commerce and everyday life. Holography is now a standard requirement in vibration analysis, image processing, holographic-optical elements, and optical computers. The potential for high-precision imaging and accurate dimensional measurement makes holography an ideal tool for in situ imaging of plankton and other microscopic-sized aquatic organisms and particles. It is this unique ability of holography to recreate, from a flat optical sensor, a three-dimensional image that is optically indistinguishable from the original that sets it apart from other imaging techniques and makes it so useful in underwater aquatic science and engineering for imaging, identification, and measurement of aquatic organisms and particles.

A detailed knowledge of the distribution and dynamics of marine and freshwater organisms and particles, such as plankton, is crucial to our understanding of the planet’s biodiversity and how these organisms affect our environment. Traditional methods of gathering in situ data on aquatic particles, such as collection using nets (which can destroy fragile organisms), electronic counting or photography, are not usually suited to observing precise spatial relationships. The overriding benefit of holography is that it permits non-invasive and non-destructive observation and analysis of organisms in their natural environment, whilst preserving their relative spatial distribution.

Initial applications of holography in underwater measurement were based on recording the holograms on photographic film or plates – so called “classical analogue holography.” This method requires wet-chemical processing of the recorded hologram together with its subsequent replay in the laboratory, on dedicated (and expensive) replay systems, to create a 3D image of the original scene. Furthermore, taking classical holography out of the laboratory and into a field environment, requires the use of short-duration pulsed lasers to reduce the effects of vibration or movement in any of the optical components or in the objects being recorded. However, this does have the advantage of freezing the scene at the recording instant, thereby allowing fast moving particles to be imaged.

With the dramatic improvements in electronic sensor technology and computer performance, digital holography (DH) – sometimes known as digital holographic microscopy (DHM) – has now begun to dominate the field of aquatic holography. In contrast to classical methods, digital holography records the hologram on an electronic sensor array, such as a charge-coupled device (CCD) or complementary metal oxide semiconductor (CMOS), and the resulting interference pattern is stored in fast computer memory. Reconstruction of the digital holographic image is carried out, in a computer, by numerical simulation of the beam propagation through the hologram and the resultant image at a particular plane in space with reference to the hologram, viewed on a monitor.

Regardless of whether or not analogue or digital recording is employed, a hologram captures vastly more data than a photograph; the reconstructed scene retains the parallax of the original and is free from perspective distortion. Image resolution is high (a few micrometres under favourable conditions) over a wide depth-of-field and field-of-view. Sequential holograms can record changes within a recording volume over a defined period of time and the wide recording dynamic range allows images to be captured that would otherwise be lost in noise. Additionally, in digital holography, “holovideos” can be produced that capture the time dimension as well as spatial dimensions.

For a general background to classical analogue holography, *Optical Holography* (Hariharan, 1996) provides a good introduction; and for the basic principles of digital holography, *Digital Holography and Wavefront Sensing* (Schnars *et al.*, 2015) and *Digital Holography and Three-dimensional Television* (Poon, 2006) provide comprehensive overviews of the techniques.

Analogue Holographic Recording and Replay

Although digital holographic recording is now the dominant method of underwater holography, it makes sense to start with an outline of classical analogue holography, since this helps to explain the concepts and bring out the crucial advantages of holography for aquatic studies. Of the possible recording methods of holography (whether classical or digital) two in particular, the “in-line reference beam hologram” (ILH) and the “off-axis reference beam hologram” (OAH), find use for high-resolution in situ imaging underwater.

In an ILH, a single laser beam (Fig. 1) is directed through the sample volume towards the sensor (photographic or electronic). The optical interference which occurs between light diffracted by the object and the undeviated portion of the illuminating beam is recorded on the sensor. A laser is needed in recording to provide the optical coherence properties necessary to produce the optical interference pattern.

Fig. 1 Recording of an in-line hologram of suspended particles.

Fig. 2 Replay of an in-line hologram.

The method of reconstructing or replaying the hologram to create a 3D image is where analogue and digital holography differ. In the analogue form, the holographic film must be placed in a replica of the original reference beam (in terms of wavelength, wavefront curvature, phase and direction) and the resultant image viewed with some auxiliary optical system such as a video camera (**Fig. 2**). The replayed hologram simultaneously forms two images, one “virtual,” the other “real,” which are located on the optic axis on opposite sides of the holographic plate. These two images are co-axial, and located (for the typical case of collimated recording and replay beams) at equal distances in front of and behind the hologram plane. The virtual image appears to be located behind the hologram and seen through it (like viewing through a window – although this should not be done since the viewer will also see the straight-through laser beam). The real image is formed in space in front of the hologram, between the hologram and the viewer. Although a true 3D real image is produced, because of the dimensions of the sensor it has almost no parallax, and cannot easily be seen by the unaided eye. This image has inverted depth perspective and is seen in darkfield against the out-of-focus virtual image. Traversing a camera through the projected real image allows optical “sectioning” of the image at any plane in the image space.

In OAH, a two beam recording geometry is utilized, although both must be generated from the same laser: one beam illuminates the scene, and the other directly illuminates the holographic film at an oblique incidence angle (**Fig. 3**). Optical interference occurs between the diffuse light reflected from the scene and the angularly separated reference beam. On replay, the real and virtual images are angularly separated which makes their interrogation easier. OAH is primarily applied to opaque subjects of large volume. To view the “virtual image” in OAH, the processed hologram is replaced in the position in which it was originally recorded and illuminated with an exact duplicate of the original reference wave, in terms of its wavelength, curvature, and beam angle. In this mode, a virtual image is observed as if viewing the scene through a window. Other than colour, this image is almost optically indistinguishable from the original scene.

Once again for data extraction and measurement, the projected “real” image (**Fig. 4**) is most useful. If we illuminate an off-axis hologram from behind, with a wave which is the exact phase conjugate of the original (i.e., one which possesses the same wavelength as the original but with the opposite direction and curvature), we generate an image that appears to float in the real space in front of the observer. Often a collimated reference beam is used in recording, since reconstruction is then a simple case of turning the hologram around. No lens is needed to form this image, and it is optically identical to the original wave save that it is reversed left-to-right and back-to-front (pseudoscopic). Planar sections of the real image can be optically interrogated by directly projecting onto a video camera (often with the lens removed) which can be moved throughout the 3D volume.

Fig. 4 Real image reconstruction from off-axis hologram.

Digital Holographic Recording and Replay

The concepts of digital holography are broadly similar to those of analogue: the main differences being the recording medium and the method of reconstruction of the holographic image. In digital holography, the interference field is stored directly into computer memory and the hologram is replayed by numerical simulation of the propagation of the optical field through space. In this way planar sections of the image can be recreated at any distance from the hologram plane, at any time, and displayed on a computer monitor, allowing size, location, identification and distribution of particles to be extracted. Computer-based algorithms are used to pre- and post-process the holograms, which are replayed and displayed on a TV monitor at any plane in the recording space. Importantly, the phase as well as the intensity of the wave field is retained on reconstruction. Apart from speed, convenience, and freedom from wet chemical processing, a distinct advantage of electronic recording is the ability to record holographic videos. This allows not only 3D spatial interrogation but allows visualisation of the movement of organisms within a particular scene and tracking the path of individuals.

For digital holographic particle sizing, the ILH mode of recording is generally the favored option by virtue of its geometric simplicity, and consequently its lower cost and potentially higher resolution. Because of the much higher sensitivity of electronic sensors compared with holographic photosensitive film, low power continuous-wave (c.w.) lasers can be used for illumination. In field applications though, pulsed lasers are often a better choice, particularly if the subject is fast-moving or subject to vibration,

or the holocamera cannot be held steady with respect to the target. To record large, opaque or dense aggregates of particles, OAH allows the use of front or side illumination of the subject in conjunction with a separate side or off-axis (angular) reference beam.

One major limitation, though, of digital recording is the lower resolution of electronic sensors compared with that of photographic film. The sensor must be able to resolve the finely spaced interference pattern recorded in the hologram; thus the grain or pixel size has a great bearing on imaging capabilities. The maximum spatial frequency of the resolvable interference pattern depends on the angle between the reference beam and the object beam. The typical grain size of 30 nm or so for holographic film is about two-orders of magnitude greater than that of a typical electronic sensor of about 3 μm pixels. Accordingly the achievable fringe frequency is much greater and reference beam angles up to 45° or so are possible with film, whereas the electronic sensor can only support beam angles up to about 10° . It is this requirement which so far makes in-line recording the dominant method of DH, since the reference beam angle is essentially zero.

Generally the computer algorithms developed for digital recording and numerical replay of a hologram are based upon the Fresnel–Kirchhoff formulation of a complex monochromatic wavefield propagating from a scene through the aperture of an optical sensor. The algorithms employed achieve computational efficiency by applying appropriate approximations and simplifications to make the Fresnel–Kirchhoff equation more suitable for digitisation and computer implementation. In most cases, the integral is implemented as a Fourier transform, thereby allowing the use of existing Fast Fourier Transform (FFT) libraries that can be easily incorporated into software. It is possible to recreate the intensity and phase distribution of the wavefield at any plane in the reconstructed volume of the hologram; thereby simulating the effect of traversing an image sensor through an optically replayed hologram (but with the added advantage that phase information can also be extracted).

Subsea Holography and Holocameras

In general, the usefulness of holography for accurate inspection and measurement is dependent on its ability to reproduce an image of the object which is low in optical aberrations and high in image resolving power. Regardless of whether or not the hologram is recorded underwater, high resolution, high contrast, and low noise are the dominant requirements. All the primary monochromatic aberrations (spherical aberration, astigmatism, coma, distortion, and field curvature) of any optical system may be present in the holographic image. For precise and accurate reconstruction of the real image, the reconstruction reference beam should be an exact copy of the original (where possible), but opposite in curvature (the phase conjugate) of that used in recording. Under these conditions, the lateral, longitudinal, and angular magnifications of the real image with all equal unity and aberrations can be reduced to a minimum.

When holography is applied subsea, the hologram is recorded in water but the image is replayed, in the laboratory (if classical) in air, or by computer (if digital). Because of the refractive index mismatch between recording and replay spaces, optical aberrations in the reconstructed image will be exaggerated, and can impair the potential for high-precision measurement. In ILH, only spherical aberration is significant since both reference and object beam angles are normal to the recording plane. However, in OAH astigmatism and coma dominate; they increase the greater the field angle of the subject in the reconstructed image. These limit resolution and introduce uncertainty in co-ordinate location. These additional aberrations are entirely due to the refractive index mismatch between object and image spaces and are unconnected with the holographic process itself. Furthermore, the water itself may be expected to influence the quality of the images produced. An increase in the overall turbidity of the water will adversely affect both ILH and OAH recording and will create background noise that will reduce image fidelity. In most underwater applications the objects (or the camera) are in motion during the exposure. The effect of this motion is to blur out the finer fringes, and thus reduce resolution and contrast.

A recurring issue in all forms of holographic recording (digital or classical) of microscopic particles, and one which imposes limits on the wider use of the technique, is extracting, processing and analyzing the vast amount of data contained in a hologram. Although analysis of classical holograms, can be performed by manual scanning of the optical reconstructions, this is tedious and time-consuming and requires high levels of concentration; automatic interrogation of the data in a dedicated reconstruction facility is essential for all practical applications of the technique. Since the main thrust of this article is on digital holography the following discussion is restricted to subsea digital methods.

Since a single holovideo may contain as much as several gigabytes of data, a first step in interpretation of digital holograms and holovideos of particles often involves localizing every particle within a frame (in x , y , z , t), and distilling particle shape and positional information from it. This facilitates application-specific processing, with subsequent image recognition, particle tracking, counting and sizing. For each video frame, the hologram is reconstructed in incremental steps and an image of each slice parallel to the sensor plane is sequentially obtained. This is equivalent to discretized simulation of the wave-field projected into real image space by an analogue hologram when reconstructed by an optical beam. When a particle coincides with a reconstruction plane it will appear in-focus, and is characterized by a maximization of image gradients at the particle edges.

Focus detection is typically the first step in hologram analysis and with suitable software, particle identification can be carried out on focused particle images and 3D plots of relative position and distribution produced. Most of these algorithms implement optimal-focus metrics which depend variously on image intensity gradient, variance, correlation, histograms and frequency-domain analysis. These metrics all rely on the premise that focused images have higher information content than blurred (out-of-focus) images due to the existence of larger gradients with higher variance across them. This leads to a greater deviation between maxima and minima in the brightness histogram and the local maximization of power in higher frequency components when the image is transformed to the frequency-domain. Due to “speckle effects” in the hologram an algorithm with good noise immunity

is required. One such algorithm relies on estimating the contour gradient around a particle and has been used to analyze a number of holographic videos recorded in the North Sea.

The first-known use of holography for recording living marine plankton was by Knox in 1966, who recorded classical in-line holograms, using a low coherence ruby laser, of a variety of living marine plankton species in a tank. Following this pioneering work, a host of subsea holographic systems, based on classical holography were developed and deployed up until the late 1990s and early 2000s (e.g., [Carder, 1979](#); [Katz 1999](#)). Although these holocameras successfully demonstrated the power and ability of the technique, they were big, bulky, heavy and not easy to deploy from research vessels or remotely operated vehicles (ROVs) and autonomous underwater vehicles (AUVs).

With the development of high-resolution electronic sensors such as CCD or CMOS together with increased power and speed of modern PCs and high storage methods, digital holography took over from the early 2000s. Now holography was freed from the constraints of laboratory replay, wet-chemical processing and could be replayed in near real-time. Other advantages included recording with low-power diode lasers (under appropriate conditions) and the introduction of the time dimension allowing holographic videos to be captured.

Digital Subsea Holocameras

The first digital holocamera for underwater applications was developed by [Owens and Zozulya \(2000\)](#). It utilized a 10 mW continuous wave (c.w.) diode laser in an in-line configuration onto a CCD array over a maximum in-water path length of 25 cm.

Fig. 5 Appendicularia (a) unreconstructed hologram, (b) reconstructed image (scale in mm).

Fig. 6 Internal layout of *eHolocam* showing the laser, power supply and computer on the right and the smaller CMOS housing on the left.

The use of a c.w. laser can be justified on the grounds that the enhanced sensitivity of electronic sensors over photofilm reduces exposure times to about 100 μ s. However, this still limits application to slowly moving systems. This holocamera was successfully deployed to depths of about 50 m in Tampa Bay, FL.

Since then, several groups world-wide have exploited DH for underwater environmental science (e.g., [Dyomin et al., 2003](#); [Jericho et al., 2006](#); [Nimmo Smith, 2008](#)); and submersible digital holocameras are now becoming commercially available. Although these systems share common elements such as use of the in-line geometry and, usually, charge-coupled device (CCD) arrays, there are subtle differences amongst them relating to their application and deployment method. Many were developed primarily for studies of phytoplankton over sampling volumes of around 1 mm³; their use of continuous lasers limits them to low particle velocities.

One such system is shown in [Fig. 5](#); and known as “*eHoloCam*” ([Sun et al., 2007](#)). It embodied a different approach from many of the others. Although still adopting in-line holography, *eHoloCam* utilized a collimated (parallel) beam from a pulsed frequency-doubled Nd-YAG. For subsea purposes, a laser with a wavelength in the blue-green region of the spectrum will match the peak transmission window of seawater. A frequency-doubled Nd-YAG laser with a wavelength of 532 nm is a good choice, although ruby lasers operating at 694 nm are also acceptable if transmission distance is not an issue. *eHoloCam* was designed with larger planktonic species in mind and featured a large recording volume of 36.5 cm³ over a 453 mm path length to allow the sparser zooplankton species to be captured rather than the more abundant, and smaller, phytoplankton.

Fig. 7 Reconstruction of a calenoid copepod.

Fig. 8 Reconstruction of a jellyfish larvae (scale is mm).

eHoloCam consists of two water-tight housings: the larger housing contains the laser, a single board computer, storage hard drives and beam forming optics (Fig. 6). The second, smaller, housing contains a CMOS sensor of 2208×3000 , $3.5 \mu\text{m}$ square pixels on a $10.50 \text{ mm} \times 7.73 \text{ mm}$ area. Both housings were designed to an operational pressure of 30 MPa (3 km depth). Sapphire windows allowed beam transmission through the water from laser to sensor. Holograms were recorded at video frame rates up to 25 Hz.

eHoloCam was deployed in the North Sea from the RV Scotia (Marine Scotland Science, Aberdeen, Scotland) on four cruises over 1 year (December 2005 to December 2006). It was operated from a sampler frame Auto-Recording Instrumented Environmental Sampler (ARIES – Marine Scotland Science, Aberdeen, Scotland) and the short pulse duration (4 ns) allowed it to be towed at up to 4 knots (about 2 m s^{-1}) to depths of 450 m. Water flows through the “jaws” of *eHoloCam* laterally and perpendicular to the beam path. The system is self-contained in power and data storage and executes embedded control software. The use of ILH and pulsed laser allowed hologram recording at energies of less than a millijoule.

Hologram frames have been reconstructed using the angular spectrum algorithm and manually extracted from the recorded holovideos. Fig. 6 shows an Appendicularia firstly as an unreconstructed hologram and then shows the reconstructed, focused image. Fig. 7 shows a calenoid copepod and Fig. 8 shows a jellyfish larvae.

Conclusions

Since its inception in the early 1960s, holography has shown itself to be particularly useful for studies of microscopic species in the aquatic environment. Its non-destructive and non-invasive nature lend itself particularly for this environment. We have seen that holography in both its classical analogue form and its digital form provides significant advances and features not present in conventional methods of imaging. These features such as 3D, optical sectioning, freedom from parallax and perspective effects, high depth-of-field all offer important benefits to aquatic biologists in their drive to understand the complexities of our aquatic environment. In particular, digital holography also offers the ability to record holographic videos which allow the preservation of the time dimension as well as particle location. Now with the improvements in electronic sensors and computer technology, in-line digital holography is well on its way to becoming a standard tool for studies of microscopic organisms in the sea. Specifically holography aids biologists in their studies of the behavior of organic species such as plankton and other marine organisms and aquatic particles in the oceans of the world. With further development holography is set to become one of the most valuable tools available for aquatic biologists.

Overview of a Holographic Display

History of Holography

Holography was invented by Dennis Gabor in 1948 for the correction of electron lens aberration to improve electron microscope resolution (Dennis, 1948). The word of holography is composed of 'holo-' and '-graphy', which stand for 'whole' and 'writing', respectively. The advantage of being able to reconstruct the wavefront in space was appreciated gradually, and the research works on various holographic applications started to develop.

The electron wave based holography was not immediately implemented in optical applications because of the lack of adequate coherent light source at the time. Mercury arc lamps were used commonly as the light source and the image quality of the holographic experiments was poor due to the low coherence of light. The situation changed completely after the laser was invented in 1960, and the first practical optical hologram with recorded 3D objects was realized in 1962 by Yuri Denisyuk in the Soviet Union (Denisyuk, 1962) and Leith and Upatnieks at the University of Michigan (Leith and Upatnieks, 1962).

Although people have been hoping to realize 3D images through holography for decades, as shown frequently in novels and sci-fi movies, there has been almost no actual implementation commercially so far. Instead, holography finds its applications in holographic optical elements (HOE), such as holographic gratings and holographic lenses, and in interferometry as a standard optical measurement technology, known as the non-destructive testing and holographic microscopy. It also found its way back in the aberration correction for optical components, as what Gabor intended to at the beginning. Furthermore, holography is used in anti-counterfeiting and authentication, such as the holograms laminated on credit cards and identification documents. It also has the potential to be used in optical data storage and optical computing. Nevertheless, this review will focus on the development and issues related to holographic displays, in particular digital holographic displays.

Principle of Holography

A light wave, or an electromagnetic (EM) wave more generally, can be described by using its amplitude and phase. Consider a certain area, such as a square or a circle, in a space which the light flux propagates through. The basic concept of holography is to record the complex light field (both amplitude and phase) in this area and then reconstruct it for various applications. This principle can also be extended to non-EM situations, such as electron waves used in the electron holography. For display applications, the light waves to be considered are in the visible range with a wavelength between 400 and 700 nm.

Recording a complex light field was done traditionally by using photosensitive materials, which response to light intensity rather than phase. Using a single coherent light source, the object light scatters from an object and interferes with the reference light in space. The interference pattern carries the information of both the amplitude and phase of the wavefront of the object light. Such a pattern is called a hologram, or to be precise an intensity hologram when recorded on the photosensitive material. To reconstruct the recorded wavefront of the object, a reference light is used to illuminate the intensity hologram from the same angle as it was recorded.

Fig. 1 illustrates the conventional way of recording a hologram and reconstructing a holographic image. Detailed mathematical description of these processes can be found in Benton and Bove (2008). In practice, it requires suitable equipment and finds experimental skills to successfully produce high quality holograms and reconstructed images.

Using intensity holograms produced by interference to record and reconstruct wavefront is not the only method of holography. The main reason to use an intensity hologram was historical because of the difficulty in modulating the phase of light directly in the past. As the technology progresses, it is now possible to use an array of mega pixels on a phase-only spatial light modulator (SLM) to form a phase-only hologram and modulate the phase of light. This allows us to manipulate the wavefront of light directly without the need to manipulate its intensity, hence the maximum light efficiency.

Both intensity and phase-only holograms can be generated by using appropriate SLMs. Digital holographic displays use those SLMs which are pixelated.

Digital Holography and Computer Generated Hologram

Holographic interference patterns, i.e., holograms, carry the information of light propagation, and can be sampled (recorded) discretely. This discrete information can be kept and reconstructed digitally, and this technique is called digital holography and the corresponding holograms and displays called digital holograms and digital holographic displays, respectively. Computer generated hologram (CGH) is a part of digital holography, and it specifically means those digital holograms which are generated by calculations on computers. Calculation of CGHs involves light propagation calculations and complex information approximation (further information see Section Computer Generated Holograms). Note that the wave information which a CGH carries can be

Fig. 1 Illustration of the recording and reconstruction of a 3D scene using holography.

any kind of light propagations, including image and beam propagations. The hardware to load CGH and reconstruct images is mostly of a pixelated structure except few exceptions, and this will be discussed in Section Hardware for a Holographic Display.

Hardware for a Holographic Display

Holograms can be recorded on photosensitive materials such as silver halide films from Geola (Zacharovas *et al.*, 2001), holographic photopolymer from Bayfol (Jurbergs *et al.*, 2009) and DuPont (Gambogi *et al.*, 1994), as described in Section Principle of Holography. These photosensitive materials are one-off use in general and not suitable for dynamic display applications (Berneth *et al.*, 2013; Bjelkhagen *et al.*, 2008; Cody *et al.*, 2012; Stevenson, 1997). Here, we will introduce only the materials and devices suitable for dynamic holographic displays, i.e., for holographic video displays.

Passively Dynamic Holographic Display Devices

One straightforward approach to display holographic images at video rate is to reconstruct sequential static images from sequential static holograms, just as the way which movies are shown using static image films. To implement this approach, updatable mediums, on which holograms can be recorded and removed repeatedly, were proposed and researched, such as a photorefractive polymer (PRP) films (Blanche *et al.*, 2010a,b; Kinashi *et al.*, 2012; Tay *et al.*, 2008) and optical addressed spatial light modulators (OASLMs) (Shrestha *et al.*, 2015; Slinger *et al.*, 2004; Stanley *et al.*, 2004) and azobenzene-based devices (Rasmussen *et al.*, 1999; Shishido, 2010). They can be regarded as passive dynamic holographic display devices (PDHDDs). “Passive” here means that the hologram information is provided from another device, and a PDHDD only carries it passively.

PRP films are simple in configuration and can support nanometer size grains, but they need high voltages ($> \text{kVolts}$) for its operation. OASLMs, on the other hand, can be operated at low voltages ($< 10 \text{ Volts}$), but with much larger reported spot sizes. Researches on both devices have improved their performance over the years, leading to better resolution, higher sensitivity, faster response time and larger area with good uniformity. A paper in 2015 shows that it is able to achieve sub-micro resolution for an OASLM (Shrestha *et al.*, 2015). In addition, updatable hologram materials have shown further potential in applications, such as data storages and futuristic optical displays for optical computing systems.

To use updatable holographic films for dynamic holographic images projection, it requires holograms to be written on the films in real time. This is not normally feasible if the diffraction patterns come from a real object directly. However, it is possible to do so if they are provided by active dynamic holographic display devices (ADHDDs), which will be introduced in the next section. Nowadays, almost all reported demonstrations of updatable holographic films are using ADHDDs to write target diffraction patterns on them.

One advantage of using a PDHDD device is that it can provide a large aperture and hologram size for the holographic image reconstruction. Existing ADHDDs all have limited apertures and hologram sizes, and this limits the minimum image spot size it can reconstruct (Hecht, 1998). The use of a PDHDD allows holograms from an ADHDD to be written and tiled up on it, to provide a better image quality in reconstruction. Nevertheless, as spatial light modulators (SLMs) develop over the time, $4\text{k} \times 2\text{k}$ chips are now commercialized (Jasper Display Corp., 2017; Texas Instruments, 2017) and $8\text{k} \times 4\text{k}$ chips are also available (Senoh *et al.*, 2013), and hence the aperture issue is of a less concern.

Active Dynamic Holographic Display Devices

An ADHDD is the kind of SLMs which modulate light directly by themselves. In holographic display applications, two types of ADHDDs are widely used, pixelated type SLMs and acoustic-optic modulators.

A pixelated SLM consists of a large number usually millions of pixels, each of them can be controlled individually to modulate either the amplitude or the phase of light in normally a digital manner. It is possible to control even both of the amplitude and phase simultaneously through cascade approaches (Hsieh *et al.*, 2007; Jesacher *et al.*, 2008a). The pixel pitch has been brought down over from 15–20 μm a few years ago to 1–5 μm now (Jasper Display Corp., 2017; Senoh *et al.*, 2013; Isomae *et al.*, 2016; Oppenheim and Lim, 1981). It is expected that the pixel pitch will become even smaller in future. Holographic images are reconstructed usually with a plane wave illuminating the holograms uploaded on the pixelated area of an SLM. Approaches to generate holograms from computation will be introduced in Section Computer Generated Holograms.

Liquid crystal on silicon (LCOS) devices are probably the most commonly used pixelated SLMs in a holographic display. LCOS combines the functionality of the cutting-edge CMOS integrated circuit technology with a nonlinear electro-optic material which could be switched by low voltages. The device operates in the reflective mode and its construction is similar to that of a liquid crystal cell apart from that a silicon backplane with a reflection layer is used in place of one of the traditional glass substrates. There are various types of LCOS, including grey-level amplitude-only, grey-level phase-only ones as well as binary amplitude-only and phase-only ones using ferroelectric liquid crystals (ferroelectric LCOSs). A cross section sketch of a typical phase-only LCOS device is shown in Fig. 2 (Zhang *et al.*, 2014). In holographic displays, phase-only LCOSs are normally used because of its high light efficiency and good reconstruction image quality (Oppenheim and Lim, 1981). Other applications of phase-only LCOSs can be found in Collings *et al.* (2011). Ferroelectric LCOSs are also often used because they have very high frame rate. Temporal based methods are used in the image reconstruction by Ferroelectric LCOS SLMs, to compensate the low image quality due to the binary nature. The advantage of LCOS SLM technology includes: benefit on the development of silicon CMOS technology, integration of high performance driving circuitry on the silicon chip, high pixel fill factor, high quality process technology for excellent pixel mirror reflectivity, and scalability to smaller feature size and higher pixel number.

Digital micro-mirror devices (DMDs) are also a widely used in holographic displays. Although a DMD can only support binary amplitude modulation, its high frame rate (up to 30 kHz (Texas Instruments, 2017)) makes it attractive since it can support a large information bandwidth for a holographic video display with large image size and viewing angle.

Apart from LCOS and DMD, there are other SLMs developed previously which are less used for holographic displays nowadays, such as liquid crystal transmissive SLMs which have low fill factors. There are also some devices under development but not yet fully realized, such as diffractive nano-devices (Sun *et al.*, 2013) and flexo-electro LCOS (Chen *et al.*, 2009).

In addition to the pixelated digital devices, an acoustic-optic modulator (AOM) has also been applied in holographic display. An AOM is an analog-type SLM without pixelation structure and it is often used in laser Q-switches (Hecht, 1998). It modulates light using the acoustic-optic effect of certain materials, which refractive index changes when an acoustic wave passes through it. The acoustic wave modulated periodic index changes form an effective grating which modulates the light accordingly. Different to a pixelated SLM, which reconstructs the object light for the whole target image simultaneously, an AOM delivers one light beam at a single time. This means that with an AOM the object light is reconstructed beam by beam. In other words, an image is generated pixel by pixel in time sequence. Well-known holographic displays built on AOM(s), the Mark system, will be introduced in Section Selected Holographic Display Systems.

Bandwidth Requirements for Decent Display Size and Viewing Angle

We define the information bandwidth of a device or display system as the product of its spatial bandwidth (number of pixels to provide at a given time) and temporal bandwidth (refresh rate or frame rate).

To generate a genuine holographic 3D image from diffraction, we can calculate how much spatial information or the number of pixels is required to support the given specifications of an image. The viewing angle, $\Delta\theta$, is:

$$\Delta\theta = \sin^{-1}(W/2d) \quad (1)$$

Fig. 2 Cross section of a typical phase-only LCOS device. Reproduced from Zhang, Z., You, Z., Chu, D.P., 2014. Fundamentals of phase-only liquid crystal on silicon (LCOS) devices. Light Sci. Appl. 3, e213.

and the image size, Δh , is:

$$\Delta h = d \sin \theta_d = d\lambda/p \quad (2)$$

where W is the SLM width in one dimension, d the distance between the SLM and the reconstructed image, θ_d the diffraction angle for the 1st order, λ the wavelength, p the hologram pixel pitch.

In the far field $d \gg W$, $\Delta\theta \sim W/2d$ and the product of Eqs. (1) and (2) gives the number of pixels required, n , as:

$$n \simeq 2\Delta h\Delta\theta/\lambda \quad (3)$$

This result is the same as that obtained from a Fourier holographic display geometry in Stanley *et al.* (2000).

Assuming the targeted viewing angle, θ , is tiled by a number of $\Delta\theta$ and the targeted image size, H , is tiled by several Δh . For a holographic display of two dimensions with the image sizes, H_x and H_y , and the corresponding viewing angles, θ_x and θ_y , respectively, the spatial bandwidth or the overall number of pixels, N_{tot} , needed to reconstruct such an image will be from Eq. (3):

$$N_{\text{tot}} = N_x N_y \simeq 4H_x H_y \theta_x \theta_y / \lambda^2 \quad (4)$$

Multiplying this number of pixels with the required frame rate will give us the necessary information bandwidth.

Considering a holographic video display with a display size of 200 mm $\times$ 200 mm, viewing angles of $30^\circ \times 20^\circ$ and frame rate of 60 Hz, it would require the system to have an information bandwidth capable of delivering at least $\sim 10^{12}$ pixels/s for just the red colour ($\lambda \sim 633$ nm). If we want to support full colour with additional green and blue, the information bandwidth required will be more than tripled.

However, existing display devices described in this section can only manage to deliver at most $\sim 10^{10}$ pixels/s, which is two orders less than that required. Besides, the available computational speed and data bus transfer rate at present are also nowhere near the levels needed for real time videos. Such hardware limitations significantly restrict the development and deployment of holographic 3D displays.

Selected Holographic Display Systems

In the last a few decades, there have been many holographic display prototypes reported. We review here a few representative systems, to illustrate how different holographic displays are developed.

QinetiQ system

QinetiQ developed a holographic 3D display which is known as the so-called Active Tiling (AT) display system (Stanley *et al.*, 2000; Slinger *et al.*, 2001), in which an electrically addressed SLM (EASLM) is used to write the hologram onto an OASLM time-sequentially. The OASLM works as the information keeper. After all the holograms are written onto an OASLM array, the images are read out at once. Because the EASLM can be driven very quickly and the OASLM array can reconstruct a hologram at a larger size, the AT system potentially can deliver several giga-pixels at once.

In 2004, QinetiQ achieved an active tiling system that combines 4 channels as shown in Fig. 3(a) (Stanley *et al.*, 2004), each of which contains one $1024 \times 1024 \times 750$ Hz binary EASLM (ferroelectric LCOS) and a 5×5 OASLM array with the total equivalent resolution of 5120×5120 . As a result, the system displayed a CGH of 20,480 pixels wide $\times$ 5120 pixels high at a pixel pitch of 6.6 μm and a frame rate for the whole hologram up to 30 Hz, which is equal to 3000 Mpixel per second. As a result, full parallax holographic images with the size of 140 mm wide were reconstructed as shown in Fig. 3(b) (Stanley *et al.*, 2004).

Fig. 3 (a) The QinetiQ 4 channel Active Tiling system; (b) image of an animated movie, showing a full parallax and 140 mm wide holographic image replayed by using a 100 Mpixel Active Tiling system. Reproduced from Stanley, M., Smith, M.A., Smith, A.P., *et al.*, 3D electronic holography display system using a 100-megapixel spatial light modulator. Proc. SPIE 5249, 297.

Mark systems

The Mark holographic systems are developed by Massachusetts Institute of Technology (MIT) Media Lab. There have been a few versions already since the first Mark I system was developed in early 1990s (Lucente, 1994; Smalley, 2006; Smalley *et al.*, 2007). The work in 2013 (Smalley *et al.*, 2013) showed anisotropic waveguide-based modulators (AWM) with more than 40 channels. Each channel can deliver equivalent to 100 million pixels per second (100 Mpixels/s). The total amount of information in pixels reaches the order of Gpixels/s. The diffracted output of light from the modulator was scanned into 2D with horizontal and vertical galvanometric mirrors. The reported holographic video monitor based on AWM is shown in Fig. 4. The holographic stereogram images were generated with a native resolution of 296 pixels $\times$ 156 pixels for one view, then the image resolution was improved to 29,600 pixels $\times$ 156 pixels by scanning, and finally to a composite resolution of 355,200 pixels $\times$ 156 pixels by stitching 12 of these images together. The size of display area is 35 mm $\times$ 20 mm. The system is still under development, and new versions of Mark IV and V are in the pipeline (Gneiting *et al.*, 2016).

National institute of information and communications technology (NICT)

NICT used 16 units of 4K $\times$ 2K-pixel SLMs to project holograms as shown in Fig. 5, with an information delivery rate in the order of 10^9 pixels/s (Sasaki *et al.*, 2014a,b). To tile multiple SLMs together seamlessly, a complex optical system is designed. The experimental device was able to produce full-parallax colourful holographic 3D at video rate of 20 fps with an image size of 74 mm $\times$ 42 mm and a horizontal viewing-zone angle of 5.6 deg $\times$ 2.8 deg. They also developed 8k $\times$ 4k LCOS chips and tilted three of them together to deliver 6 billion pixels/s and create a real time holographic 3D colour display (Senoh *et al.*, 2013, 2014).

Agency for science, technology and research (A*STAR)

In comparison with the NICT system, A*STAR system not only used physical tiling but also employed optical scan-tiling of high-speed SLMs to increase the total pixel count of holograms, as shown in Fig. 6 (Lum *et al.*, 2013). 24 units of high-speed ferroelectric LCOS of 1280 $\times$ 1080 pixels in resolution were physically tiled to form a 3 $\times$ 8 SLM array. The optical output from this array was tiled in space to form a large image equivalent to that of 36 $\times$ 8 SLMs by using a horizontal galvanometric scanning mirror with 12 steps. A large computer-generated hologram for the 3 $\times$ 8 SLM array was calculated and divided to upload onto

individual SLMs (Pan *et al.*, 2013). A full-colour and full-parallax three-dimensional image of 10 in. in width was projected at a rate of 60 frames per second.

Tokyo university of agriculture and technology (TAUT)

TAUT developed a one-dimensional (1D) scanning approach called screen-scanning system, which consists of two orthogonally aligned cylindrical lenses (Takaki *et al.*, 2015; Takaki and Okada, 2010, 2009). The sub-holograms generated from a DMD was de-magnified in the horizontal direction and magnified along the vertical direction. The vertically expanded elementary holograms were then scanned horizontally using a galvanometric scanner onto a vertical diffuser screen to achieve a large screen size. As the pixel pitch is de-magnified horizontally, the horizontal viewing angle is enlarged. The vertical parallax is removed by the use of the vertical diffuser, making this display system one of the “horizontal parallax only” (HPO) systems. An illustration of the system is shown in Fig. 7 (Takaki and Okada, 2009).

Besides, TAUT also developed the resolution distribution technique (Takaki and Hayashi, 2008) and the viewing-zone scanning system (Takaki and Fujii, 2014). The resolution redistribution applies multiple shifted light sources to re-shape the effective reconstructed window, which is more suitable for one direction scanning. The viewing-zone scanning system employs a magnification image system to increase the hologram in both horizontal and vertical direction. In this case, the viewing angle is reduced. Then the reduced viewing zone is scanned by the horizontal scanner to enlarge the viewing zone, as shown in Fig. 8 (Takaki and Fujii, 2014).

Course integral holographic display (CIH)

CIH display uses coarse integral optics to angularly tile low spatial bandwidth sub-holograms to form 3D images of a decent size with full parallax features and wide viewing angles in both horizontal and vertical directions, as shown in [Fig. 9](#) ([Chen et al., 2016](#)). The result reported in 2015 ([Chen et al., 2016](#)) showed full-colour holographic 3D images consisting of 141.6 Mpixels for each colour with a size of 49.6 mm × 49.6 mm, a frame rate of 23.33 Hz and viewing angles of $12^\circ \times 3.2^\circ$. Compared with integral imaging and holographic display, CIH has a better performance on producing accommodation depth cue than integral imaging, and larger viewing angles than that of a normal holographic display.

A diffraction-based scanning 3D colour video holographic display

A diffraction-based scanning 3D colour video holographic display was developed employing tiled gratings and a vertical diffuser, as shown in [Fig. 10](#) ([Jia et al., 2017](#)). Its main idea is to use a rotational tiled grating, which is slim and lightweight, to replace a galvanometer or polygon mirror, both of which have a limited scanning speed. It can significantly increase the distributing capability of the scanner, and accommodate the information provided from a high-speed SLM, such as a DMD, without any waste. Its result reported in 2017 ([Jia et al., 2017](#)) showed a full colour HPO holographic display projecting 3D images with the size of 60 mm × 30 mm and horizontal viewing angle of 37° at a frame rate of 75 Hz.

A scalable diffraction-based scanning 3D colour video display as demonstrated by using tiled gratings and a vertical diffuser. *Scientific Reports* 7, 44656.

360 degrees holographic display

Apart from the most common front-viewing holographic display systems, there are various systems to produce images with a horizontal viewing angle of 360 degrees (full-around) (Butler *et al.*, 2011; Inoue and Takaki, 2015; Jones *et al.*, 2007; Kakue *et al.*, 2015; Miyazaki *et al.*, 2012; Sando *et al.*, 2016; Takaki and Nakamura, 2014; Takaki and Uchida, 2012; Xia *et al.*, 2013; Yoshida, 2016). This requires a huge amount of data and an information distribution system with high capacity. DMD (s), which can provide a high frame rate, are often used in 360 degrees system for prototype demonstrations. For the information distribution system, there are various approaches, such as the uses of array of projectors (Inoue and Takaki, 2015), tilted mirror (Sando *et al.*, 2016) and parabolic mirror (Butler *et al.*, 2011; Kakue *et al.*, 2015), respectively.

Holography can be integrated with the concept of 360 degrees viewing to support accommodation cue for every view (Inoue and Takaki, 2015; Lim *et al.*, 2016; Teng *et al.*, 2012). A rotating tilted mirror was used to distribute holographic images projected from a high speed SLM (Teng *et al.*, 2012). A parabolic mirror was also used to project a floating holographic image on the table (Lim *et al.*, 2016). The largest diameter of the screen was 35.2 mm among these systems. To support a large image size, a large mirror is necessary but it will increase the weight of the rotation component and slow down the scanning speed. The rotating off-axis lens, which can be made light-weight, was used to distribute holographic images to 360 degrees (Inoue and Takaki, 2015).

To summarise, a comparison of the bandwidth property of the selected holographic displays is shown in Fig. 11. The bandwidth improving strategies are spatial tiling, temporal tiling or hybrid tiling methods. No matter which technology is used for a holographic display, the most fundamental principle is to utilize the information bandwidth, in other words, the total amount of information which the device can provide per second to reconstruct holographic images.

Light Sources

Light sources for holographic displays are also developed to improve the quality of holographic images. Holograms, which takes the advantage of interference and diffraction to reconstruct images, require a coherent light source. However, a high level of coherence also produces speckle as a side-effect. To reduce speckle, various approaches are proposed. Some of them are to search a suitable light source (Kozacki and Chlipala, 2016; Mori *et al.*, 2014; Pan *et al.*, 2014; Pang *et al.*, 2015; Zhao *et al.*, 2012), which has an appropriate coherence (low enough to reduce the speckle but high enough to maintain the image quality). Although the image sharpness and speckle are related to both spatial and temporal coherences, studies show that the spatial coherence can be linked directly to the image sharpness and the temporal coherence to the speckle (Deng and Chu, 2017). To provide more natural colour from holograms, lasers with a wide range of wavelengths are researched (Sarakinis *et al.*, 2013) to refine the colour match and the commercial light sources for holography are also developed (Bjelkhagen and Brotherton-Ratcliffe, 2014). Currently, these sources already exist, and the challenge is to reduce its cost (by searching for a cheaper alternative or simplifying its fabrication) and make them affordable.

Fig. 11 The bandwidth property of selected holographic display systems.

Computer Generated Holograms

The process of calculating a digital hologram has three steps: (1) define the data of the object to be reconstructed, which can be a virtually created object or the graphic data of a real object; (2) calculate the complex field propagated from the object to the hologram plane according to the wave propagation principles; (3) transfer the calculated hologram onto a film or a SLM, using a phase-only, amplitude-only, binary or any specific format.

In general, the films or SLMs cannot control the amplitude and the phase of a complex field simultaneously, unless using some cascaded approaches mentioned earlier (Hsieh *et al.*, 2007; Jesacher *et al.*, 2008a).

To transfer hologram on films, there are techniques to encode and decode the complex field information of the targeted wave plane: detour holograms and kinoform holograms. The detour-phase hologram, which was invented by Brown and Lohmann, (1969), is a technique transforming the complex information into binary patterns printable by most plotting devices. The principle of making a detour-phase hologram is to divide the hologram into separate cells, each of which contains several pixels. The total number of pixels of the "on" state represents the amplitude and the positions of these pixels encode the phase. Note that although it is named as "phase", detour-phase technique is an amplitude modulation approach. It produces an approximation of the planned modulation and involves with errors, and it has been less used after SLMs being widely used.

The detour-phase technique was later replaced by phase contour interferogram proposed by Lee (1979, 1974). Phase contour interferogram is an encoding approach, which plots the pattern along the hologram phase contour. It can be adapted to plotters to produce a better approximation than that of detour-phase technique. It can also be applied on amplitude-only SLMs which can modulate the intensity in grey levels pixel by pixel.

Unlike pure amplitude modulations, the kinoform hologram supports a pure phase modulation and provides a better efficiency (Lesem *et al.*, 1969). The concept of kinoform holograms is based on an assumption that the phase carries the majority of information about the objects and the loss of amplitude information is acceptable (Oppenheim and Lim, 1981).

Along with the development of SLMs, amplitude-only and phase-only SLMs are commercialized and easily available. The name of detour, contour and kinoform are less used and people simply call amplitude-only or phase-only holograms. Interestingly, while DMD, a popular SLM for holographic displays, is a binary device, it does not apply detour hologram techniques. One reason is that detour-phase hologram has a limited accuracy. Besides, the necessary pixel count per second for a holographic image is high, and it is preferred to keep each pixel as one independent cell, rather than to spend multiple pixels to form an equivalent cell.

Overall, the transformation from a complex hologram to a phase-only, amplitude-only, detour or binary hologram (either phase or amplitude) is only after the complex wave propagation calculation is done. To calculate the complex amplitude and phase, there are mainly two principles. One is to adopt the wave propagation equation on each object element (point, polygon, etc.) and calculate their accumulation on the hologram plane. Another is to simply take the Fourier transformation (FT) of the target 2D image as the hologram, since the reverse FT of this pattern is the target 2D image. This corresponds to the optics fact that two planes on both sides of a lens are FT of each other. Since Fourier hologram is easier to calculate and it becomes the common implementation for 2D image hologram projection. Following we will introduce algorithms about the complex hologram calculation in 2D/2.5D/3D images.

Phase Retrieval Approach for 2D Images

To calculate holograms, we should have both amplitude and phase information of the object light. The intensity of an object is fixed according to the target while the phase of the object light at the object surface can be changed to the arbitrary number since

eyes cannot directly detect the phase of light. Meanwhile, most films and SLMs cannot modulate amplitude and phase of light simultaneously (note that there are few approaches can do this, but they still cannot be widely used). In the phase-only modulation case, the amplitude information of the calculated hologram is lost and this directly degrades the reconstruction quality of the image. Since the phase of object light is flexible, it is possible to find a phase pattern to form a phase-only hologram, which has the least loss of image quality. This action of searching is called “phase retrieval”, which is an optimization problem. The fast Fourier transformation (FFT) is the common mathematics tool used in phase retrieval. However, the FFT assumes that a hologram is an infinitely periodic arrangement without considering the aperture effect, hence the pixels in the Fourier plane may be wider than expected and overlap with each other. The consequent noise is on the image plane. Therefore, a multiple iteration method is necessary to minimise this problem.

Gerchberg-Saxton (GS) algorithm is probably the most famous approach for phase retrieval (Gerchberg and Saxton, 1972). The principle of GS algorithm is to calculate the converging solution through iterative FFT between two planes by fixing the amplitude components in one plane (the 2D image plane) and optimize the phase components in the other plane (the hologram plane). Please refers to Gerchberg and Saxton, (1972) for detailed procedure steps.

Different improvements of the GS algorithm have been proposed. The Fienup algorithm (Fienup, 1978) accelerates the converging speed by feeding the errors between the actual reconstruction image and the target image as a feedback into the iteration process. The Fienup with don't-care (Fidoc) method was proposed in 1986 (Akahori, 1986) and the further improved one in 1990 (Wyrowski, 1990). It is a specific case of the Fienup algorithm by applying the don't-care area on the image plane. The don't-care areas may be placed around or within the image, which is well known as zero padding and zero circumscribing. The Fidoc algorithm performs better than GS and Fienup algorithms in terms of image quality but at the cost of increased computational load and number of pixels because of the additional noise disposal area.

In commercialization, a handheld holographic video projector with 60 Hz frame rate and real-time CGHs was developed in CAPE of Cambridge University and demonstrated by Alps Electric in Japan in 2006, as shown in Fig. 12 (SPIE, 2017).

Holographic Stereogram for 2.5D Images

Between 2D and 3D images, we should also define the 2.5D image. By 2.5D we mean that it provides some but not all depth cues for 3D visual perception. For example, a display using multiple 2D images can provide motion parallax for 3D perception but there is a lack of accommodation cue. Stereogram, which provides 3D perception by binocular cue, is another example of a 2.5D image.

Fig. 12 A handheld holographic video projector with real-time CGHs developed in CAPE of Cambridge University and made by Alps Electric in Japan. Reproduced from SPIE, 2017. Available at: <http://spie.org/newsroom/1015-projection-display-using-computer-generated-phase-screens?highlight=x2408&ArticleID=x20068> (accessed 21.05.17).

The concept of multiple 2D images is also used in holographic display, and it is known as holographic stereogram. In early days, it records 2D pictures of the object taken from different angles onto different parts of the hologram by moving a slit step by step (Benton and Bove, 2008). Later on in 1980s, computer calculation of holographic stereogram was also realized. The principle of implementation is to divide the hologram into multiple segments as the basic elements, get the 2D projection with different angles of the 3D object on the hologram plane to get the ray information, transform the ray information (including intensity and angle) to the diffraction pattern on each segment, and then form the final hologram. The way to transform a ray into a diffraction pattern is to conduct Fourier transformation (FT) on a 2D image representing the ray direction and intensity in the image domain. Since the diffraction calculation can be done by FFT, the calculation load of computer holographic stereograms is much less than that of the conventional CGH techniques for 3D images (which will be introduced in Section 3D Images (Point/Polygon/Layer Based Methods and Improvements)).

Another advantage of holographic stereogram is that it can produce occlusion effect directly because of its use of 2D projection of the 3D object, and it can be integrated with 3D graphics without much additional computation (Barabas *et al.*, 2011; Sando *et al.*, 2013), while occlusion culling methods for conventional 3D image hologram calculation involves with heavy computation (Ichikawa *et al.*, 2013a,b; Matsushima and Kondoh, 2004; Matsushima and Nakahara, 2009; Underkoffler, 1997; Zhang *et al.*, 2011).

The concept of using individual rays is an approximation to the 3D wave propagation. To improve this approximation, phase-added stereogram was proposed (Gao *et al.*, 2015; Kang *et al.*, 2016; Yamaguchi *et al.*, 1993). It calculates the directional information of the light from the object and uses a phase factor to yield a better coherent wavefront. As a result, the depth range of the image is wider while the amount of calculation stays almost the same. In commercialization, Geola and Zebra Imaging print customized 3D holographic stereogram holograms.

3D Images (Point/ Polygon/Layer Based Methods and Improvements)

To calculate the complex wave plane of one object, the information of location and intensity should be considered. The object data can come from a virtual object or the graphics data reconstructed from a real object by a 3D camera. To simplify the calculation procedure, a 3D object is broken down to smaller basic units and the wave propagation of each unit is calculated and added up to form the final hologram.

According to the type of the basic unit in use, 3D image CGH methods can be classified into three categories. One is the point-source method, which samples 3D objects by cloud points (Eldeib and Yabe, 1996; Stein *et al.*, 1992). Another is the polygon-based method (Matsushima, 2010, 2008; Matsushima and Shimobaba, 2009), which discretizes 3D objects into a number of polygons, usually triangles. The third one is image-based approach (Barabas *et al.*, 2011; Chen and Chu, 2015; Jia *et al.*, 2014) which hybrids graphic rendered 2D images with other approaches to generate 3D effects.

The point-based method is also known as the coherent ray tracing (CRT) method. It treats every point on the object as a self-illuminating point source and calculates the emitted spherical wave to all the pixels on a hologram plane using a light propagation function (Matsushima and Takai, 2000; Nishitsuji *et al.*, 2015; Weng *et al.*, 2011). To support a high quality 3D image, the object needs to be sampled with a large number of points and this leads to a high computational load.

To improve the calculation speed, Lucente proposed the look-up-table (LUT) method in 1993 (Lucente, 1993) to store all the possible diffraction patterns for the points offline. The point diffraction patterns are directly read out from the table during the online calculation. However, the necessary size of the LUT is huge, such as hundreds of gigabytes, and it is overwhelming even for a modern computer. Several improved LUT methods (Gao *et al.*, 2015; Dong *et al.*, 2014; Jia *et al.*, 2013; Jiao *et al.*, 2017; Kim and Kim, 2008; Kim *et al.*, 2013, 2012, 2008, 2015; Kwon *et al.*, 2016; Pan *et al.*, 2009) were proposed to reduce the memory size down to the order of kilobytes.

Another method to improve the calculation speed of point-based methods is the wave recording plane (WRP) technique developed by Phan *et al.* (2014) and Shimobaba *et al.* (2009, 2010). A WRP is a virtual plane that is located at a near distance to the objects. Because the short distance and the limited diffraction angle, each object point will only diffract light within a small area onto the WRP. Then the information on the WRP propagates to the hologram plane by Fresnel diffraction. With the WRP technique, a hologram of 2048×2048 pixels in size, representing an image scene composed of 4×10^6 points, can be generated in less than 25 ms (Tsang *et al.*, 2011).

On the other hand, in the polygon-based method, the 3D object is represented by thousands of polygons rather than millions of points. It essentially reduces the number of basic units while the computation for each basic unit becomes more complicated. The computation of a polygon unit involves a rotational transformation in the frequency domain to get the pattern corresponding to the normal angle, and the angular spectrum approach which can calculate the complex information along the propagation axis (Matsushima, 2008). In 2008, a fully analytical method was developed (Ahrenberg *et al.*, 2008). It proposes a new structure to conduct polygon based methods (FFT is no longer used). The method was implemented on GPU for parallel computing in order to achieve a faster speed and better image quality (Liu *et al.*, 2010). When polygon-approach was developed, the overall calculation speed was expected to be faster than that of other approaches. However, point-based and image-based methods were also improved, and now polygon-based approach remains the slowest approach.

The image-based approach was firstly used in holographic stereogram to provide multiple 2D images for different views. This approach, later on, is applied to the calculation of real 3D images. A hybrid of point-based approach and image-based approach was proposed (Barabas *et al.*, 2011; Jia *et al.*, 2014), so that the occlusion cue is provided by graphics while the accommodation cue

is provided by point-based method. The layer-based method was also proposed (Chen and Chu, 2015; Chen *et al.*, 2014). It uses 2D rendered depth map to divide a 3D image into several layers. The hologram of each 2D image is calculated, by adding a lens of a specific focal length to the FT of that layer. Finally, holograms of individual layers are added together to form the hologram of the 3D image. It takes advantage of the factor that eyes have a limited resolution of accommodation cue, so few layers are enough to project a good accommodation cue. Research shows that only 28 depth layers are required to produce a full depth of field from 25 cm to infinite distance for human eyes (Akeley, 2004; Rolland *et al.*, 1999).

Error Reduction in CGH

Existing SLMs, such as LCOS, can only display either the amplitude or the phase component of light. The loss of either amplitude or phase information brought up the phase retrieval issue, as discussed in Section Phase Retrieval Approach for 2D Images. Different phase retrieval approaches, such as GS and Fienup methods, optimize the reconstruction image quality by using an iterative calculation. In contrast, the loss of either amplitude or phase information may lead to heavy errors in the holograms calculated by using wavefront propagation functions discussed in 3D Images (Point/Polygon/Layer Based Methods and Improvements). The random phase was first added to the object points prior to the generation of the digital hologram to minimise this error, but the random phase makes the speckle noise worse (Pan *et al.*, 2014; Makowski *et al.*, 2016; Shimobaba *et al.*, 2016,a,b; Takaki and Taira, 2016; Takaki and Yokouchi, 2011).

One solution to this problem is to cascade two SLMs and reconstruct the complex amplitude hologram (Hsieh *et al.*, 2007; Leportier *et al.*, 2016). In some implementations, an optical element (can be a prism or grating) is used to merge the wave propagations from different regions of the same device in order to achieve the complex modulation (Jesacher *et al.*, 2008a,b; Liu *et al.*, 2011; Song *et al.*, 2012). Another effective approach is to place a moving diffuser at the imaging plane (Kuratomi *et al.*, 2010; Pan and Shih, 2014). It can average the noise, but requires an extra mechanical device.

To deal with this problem through calculation, the error reduction methods are proposed which can be grouped into temporal-based and spatial-based methods. For the temporal-based method, multiple sub-frames, each of which represents the same object scene added with different random phase patterns, are displayed rapidly in sequence to the observers to average the speckle noise (Buckley, 2011; Buckley *et al.*, 2006). It is also known as the random averaging method. The superposition of N holograms with uncorrelated phase patterns can reduce the speckle noise to $1/\sqrt{N}$ at the cost of computational load and the reduction of effective frame rate.

The spatial-based error reduction method is also known as the error diffusion method (Tsang and Poon, 2013; Tsang *et al.*, 2014). It converts a digital complex hologram into a phase-only hologram without using a random phase pattern. The process is accomplished with an error diffusion mechanism. It scans each hologram pixel sequentially, updates it with the values it was past to, then pass the error to the unvisited neighborhood, and then carry on. Compared with the temporal-based method, this method does not consume the frame rate of the SLM, and the reconstructed images are very similar to those obtained with the original complex holograms. The downside of spatial-based error distribution is its additional calculations. It is noted that the error diffusion methods can be applied directly on an existing complex amplitude hologram, without knowing the original data of the object image. This allows it to be applied on holograms calculated by any approach as a post-processing approach.

Holographic Display VR/AR

Virtual reality (VR) has been a technology dream for decades. It is now gradually commercialized after the launches of Oculus Rift, HTC Vive and Sony PlayStation VR between 2015 and 2016. At the same time augmented reality (AR) is also attracting public attention. One of the representative examples is Microsoft HoloLens, released in 2016. It successfully applies a holographic waveguide combiner to be part of the AR headset while the image contents stay as 2D. On the other hand, holography can be used as true 3D image projectors and it attracts efforts on building a prototype of holographic HMD. This section introduces these two holographic applications in VR/AR.

Holographic Waveguide/Lightguide Combiner in VR/AR HMD

In early 1990s, the concept of a holographic waveguide display was patented in which a waveguide hologram was used to couple a collimated image into a glass-based waveguide, and transmit the images by Total Internal Reflection (TIR). The spectral and angular Bragg selectivity is the key functionality in the holographic combiners both in reflective or transmission holograms. Compared with a transmission hologram, a reflective hologram can achieve a narrower spectral bandwidth and a wider angular bandwidth at the same time. A larger angular bandwidth can produce a larger field of view, and narrower spectral bandwidth can reduce the chromatic aberration.

Since the waveguide can be made very thin and light, there are companies such as Sony Ltd, Konica/Minolta and Nokia/Vuzix which have applied this concept to the HMDs. Their works mainly focused on improving the light efficiency and reducing the chromatic aberration in waveguide due to the wavelength dependency of holograms.

Fig. 13 Sony holographic waveguide combiner. Reproduced from Mukawa, H., Akutsu, K., Matsumura, S., 2008.8.4: distinguished paper: A full color eyewear display using holographic planar waveguides. In: SID Symposium Digest of Technical Papers 39, pp. 89–92.

Fig. 14 A holographic 3D head-mounted display. Reproduced from Chen, J.-S., Chu, D.P., 2015. Improved layer-based method for rapid hologram generation and real-time interactive holographic display applications. Opt. Express 23, 18143–18155.

In Sony and Konica/Minolta's holographic waveguide combiners, the traditional reflective holograms are used with high diffraction efficiency because of the Bragg selectivity. The chromatic aberration in waveguide can be compensated by using three superimposed holograms, such as in Sony's approach shown in [Fig. 13](#) ([Mukawa et al., 2008](#)). Each hologram is exposed to a specific wavelength. Otherwise, Konica/Minolta and other researchers exposed one hologram three times to different wavelengths with the corresponding illuminating angle ([Kress and Starner, 2013](#); [Shi et al., 2012](#)). One drawback of using holographic waveguides is its low diffraction efficiency due to the material limitation, and its use in HMDs is replaced by free space ([Zhou et al., 2017](#)), free-form optics ([Hu and Hua, 2014](#); [Hua and Javidi, 2014](#)) or prisms ([Love et al., 2009](#)).

Holographic 3D Display in VR/AR HMD

Conventional stereoscopic HMDs may cause eye fatigue because of the conflict of accommodation and convergence depth cues. Applications of holographic 3D displays in HMD is one solution to provide accommodation cue and remove the fatigue.

A number of prototypes have been built ([Chen and Chu, 2015](#); [Li et al., 2016](#); [Tanjung et al., 2010](#); [Yoneyama et al., 2014, 2013](#)). The concept of a holographic 3D HMD is shown in [Fig. 14](#) ([Chen and Chu, 2015](#)), in which the holographic 3D images generated by the SLM are projected into human pupil directly. The necessary bandwidth (both optical and computational) for a holographic HMD is much less than that of a holographic display because of the small size of a pupil, therefore holographic HMDs are much more feasible in terms of bandwidth. Nevertheless, there are still issues remain to be solved, including speckle noise, small field of view (FOV), chromatic aberration and small eye-box. This field is still relatively new, and its development will take time before any solid impact is produced.

Key Challenges and Conclusions

Although huge efforts and funding have been put into the development of digital holographic displays for several decades, the process of its commercialization is still very slow. The key challenge is that the user experience, including the image size, viewing angle and image quality, is not as good as that of traditional 2D displays. In comparison with 2D displays, a high quality 3D

display requires a pixel size smaller than $1\ \mu\text{m}$ and information bandwidth larger than 10^{12} pixels/s for a decent size display screen. This is difficult to achieve by the existing technology. Such a huge amount of data also leads to the heavy computational load for rendering the 3D data and generate CGHs. Moreover, it is difficult to realize the real-time display because of the limited data transmission bandwidth of the data bus. For example, a DMD can run at a high frame rate but pre-uploading of the images is required, which can take a couple of minutes or even more.

To move holographic 3D display technologies forward into a mass market is not easy. We need to develop suitable technologies and products to overcome all the obstacles. Fortunately, future SLMs have the potential to be made with sub-micron pitches (Shrestha *et al.*, 2015; Isomae *et al.*, 2016) and to be driven at a fast speed (Forth Dimensions Displays, 2017), in order to produce the required amount of data. High speed computers and fast CGH calculation algorithms make it possible to generate holograms in real time (Ichihashi *et al.*, 2012), and customized data board for transmitting holograms may solve the data bus issue.

Finally, to reconstruct only the wavefront at the eye position using eye-tracking technology can significantly reduce the amount of information to be processed. Similarly, applying digital holographic 3D technology for HMDs requires much less amount of information if compared with traditional holographic 3D displays.

Holography: Computer Generated Holograms

From the Classical Hologram to the Computer Generated Hologram: CGH

Holography is a method to form images. The method consists of two steps: recording and reconstruction. In the recording step, some interference fringes are recorded on a photographic plate (Fig. 1(A)). The two interfering waves come from the object and from a reference light source. After being developed by the usual photo-chemical treatment the photographic plate is called a hologram. In the reconstruction step, the hologram acts as a diffracting object that is illuminated by a replica of the reference light. Due to diffraction, the light behind the hologram is split into three parts (Fig. 1(B)). One part proceeds to the observer who perceives a virtual object where the genuine object had been during the recording step.

This was a brief description of “classical – holography”. In “computer holography” the first step, recording, is synthetic. In other words, the propagation of the light from the object to the photographic plate is simulated digitally. The simulation includes the addition of the object wave to the reference wave and the subsequent modulus square process, which describes the transition from the two complex amplitudes to the hologram irradiance:

$$|u_O(x) + u_R(x)|^2 = I_H(x) \quad (1)$$

The amplitude transmittance of the hologram is

$$T_H(x) = c_0 + c_1 I_H(x) = c_1 u_O u_R^* + \dots \quad (2)$$

The coefficients c_0 and c_1 have to do with the photochemical development. In the reconstruction process (Fig. 1(B)) the transmittance T_H is illuminated by the reference beam. Hence, we get

$$u_R(x) T_H(x) = c_1 u_O(x) |u_R(x)|^2 + \dots \quad (3)$$

If the reference intensity $|u_R(x)|^2$ is constant, this term represents a reconstruction of the object wave $u_O(x)$. The omitted parts in Eq. (2) and in Eq. (3) describe those beams that are ignored by the observer (Fig. 1(B)). The hologram transmittance $T_H(x)$ is an analog signal:

$$0 \leq T_H \leq 1 \quad (4)$$

Fig. 1 Holographic image formation in two steps: (A) Recording the hologram. (B) Reconstructing the object wave.

[†]Deceased.

50 years ago, when computer holograms were invented (Brown and Lohmann, 1966; Lohmann and Paris, 1967), the available plotters could produce only binary transmittance patterns. Hence, it was necessary to replace the analog transmission $T_H(x)$ by a binary transmission $B_H(x)$. That is possible indeed, without loss of image quality. In addition, binary computer holograms have better light efficiency and a better signal-to-noise ratio. They are also more robust when being copied or printed.

Another advantage of a computer generated hologram (CGH) is that the object does not have to exist in reality. That is important for some applications. The genuine object may be difficult to manufacture or, if it is three-dimensional, difficult to illuminate. The CGH may be used to implement an algorithm for optical image processing. In that case, the term “object” becomes somewhat fictitious. We will discuss more about applications, in Section Some CGH Applications, towards the end of this entry.

From a Diffraction Grating to a Fourier CGH

Now we will explain, in some detail, the “Fourier type” CGH. Fourier holograms are more popular than two other types: “image-plane” CGH’s and “Fresnel-type” CGH’s. The Fresnel-type will be treated in a section on “software” because of some interest in 3-D hologram’s (Section About some CGH algorithms). Certain hardware issues will appear in Section On Some Hardware Aspects.

The explanation of Fourier CGH’s begins with grating diffraction (Fig. 2). The only uncommon feature in Fig. 2 is the off-axis location of the source. It is arranged such that the plus-first diffraction order will hit the center of the output plane.

We will now convert a simple Ronchi grating (Fig. 3(A)) into a Fourier CGH. The Ronchi grating transmittance can be expressed as the Fourier series:

$$G(x) = \sum_{(m)} C_m \exp\left(\frac{2\pi i m x}{D}\right); \quad C_0 = \frac{1}{2}; \quad C_m = \frac{\sin(\pi m/2)}{\pi m} \quad (5)$$

Fig. 2 Grating diffraction, but with an off-axis source.

Fig. 3 Modifying a grating into a hologram in 3 steps: (A) Ronchi grating. (B) Modified width and location of the grating bars. (C) Distorted grating bars. (D) As in Fig. 3(C), but now discrete modifications.

Now we shift the grating bars by an amount PD . And, we modify the width from $D/2$ to WD , as shown in Fig. 3(B). The Fourier coefficients are now

$$C_m = \frac{\exp(2\pi i m P) \sin(\pi m W)}{\pi m} \quad (6)$$

The C_{+1} coefficient is responsible for the complex amplitude at the center of the readout plane:

$$C_{+1} = \frac{\exp(2\pi i P) \sin(\pi W)}{\pi} \quad (7)$$

We are able now to control the beam magnitude, $A = (\frac{1}{\pi})\sin(\pi W)$, by the relative bar width W and the phase $\phi = 2\pi P$ by the relative bar shift P . This particular kind of phase shift is known as “detour phase” (Hauk and Lohmann, 1958).

So far, the light that ends up at the center of the exit plane, leaves the grating as a plane wave with a wave vector parallel to the optical axis. Now we distort the grating on purpose (Fig. 3(C)):

$$W \rightarrow W(x, y); P \rightarrow P(x, y) \quad (8)$$

These distortions should be mild enough that the plus-first order light behind the distorted grating can be described by the complex amplitude:

$$\left(\frac{1}{\pi}\right) \sin[\pi W(x, y)] \exp[2\pi i P(x, y)] = u_H(x, y) \quad (9)$$

This is a generalization of Eq. (7). The phase $2\pi P(x, y)$ covers the range from $-\frac{\pi}{2}$ to $\frac{\pi}{2}$ if the shift is bounded by $|P| \leq \frac{1}{2}$. That is enough to cover the range of complex amplitudes within the circle of $|u_H| \leq \frac{1}{\pi}$. We will return shortly to the condition “mild-enough distortions” in the context of Fig. 4.

Most plotters move their pens only in x -direction and y -direction and printers place dots on a grid. Therefore it is convenient to replace the continuous (x, y) variations of W and P by piece-wise constant variations as in Fig. 3(D). That restriction turns out to be acceptable, as demonstrated by the first computer holograms. The theoretical proof involves the sampling theorem (Lohmann and Paris, 1967).

Recall that the light propagation through a 2-f system (Fig. 2, between grating and output plane) can be described by a Fourier transformation:

$$\iint u_H(x, y) \exp[-2\pi i (xx' + yy')/\lambda f] dx dy = \tilde{u}_H(x'/\lambda f, y'/\lambda f) \quad (10)$$

Suppose now that we wish to see a particular image: $v(x', y')$. Hence, we request that

$$v(x', y') = \tilde{u}_H(x'/\lambda f, y'/\lambda f) \text{RECT}(x'/\lambda f) \quad (11)$$

The RECT function indicates that only the PLUS first diffraction order is of interest. As a consequence we have to select the grating distortions $W(x, y)$ and $P(x, y)$ such that the hologram $u_H(x, y)$ is the Fourier transform of $v(x', y')$:

$$u_H(x, y) = \iint v(x', y') \exp[2\pi i (xx' + yy')/\lambda f] dx' dy' \quad (12)$$

Fig. 4 CGH with 64×64 cells.

Fig. 5 A reconstruction from a 1024×1024 CGH. The true image and the symmetrical twin image appear. The zeroth-order is blocked. Reproduced from Brown, B.R., Lohmann, A.W., 1969. IBM J. R&D 13, 160.

Fig. 6 Reconstruction setup for a Fourier CGH.

The condition “mild enough distortions” has been treated in the literature. There is not enough space here to present that part of the CGH theory. But we show an actual CGH with 64×64 cells (**Fig. 4**). This CGH is no longer a grating. But, it shows enough resemblance to our heuristic derivation. Hence, the CGH theory appears to be trustworthy. A CGH looks less regular if the image $v(x', y')$ contains a random phase that simulates a diffuser. The diffuser spreads light across the CGH and so levels out unacceptably large fluctuations in the amplitude.

With 512×512 or 1024×1024 cells in a CGH one can obtain an image of the quality seen in **Fig. 5** (Brown and Lohmann, 1969). The reconstruction setup is shown in **Fig. 6**, here with the letter F as the image.

About Some CGH Algorithms

The computational effort for getting the desired hologram amplitude of a Fourier hologram u_H is reasonable due to the powerful FFT algorithm. To use it the data must be discrete. In other words the CGH consists of cells, centered at $x_m = mD$, $y_n = nD$ as shown in **Fig. 3(D)**. The questions now are: “What is the proper cell size D ?” and “How many cells are needed?” The answers to those questions depend on the parameters of the image. If the zero order (see **Fig. 6**) should be at the distance Δx_0 , then the quasi-grating period D should obey:

$$\lambda f / D \geq \Delta x_0 \quad (13)$$

And if the size of an image pixel should be as fine as δx_0 the size Δx_H of the hologram should obey:

$$\lambda f / \Delta x_H \leq \delta x_0 \quad (14)$$

This condition is plausible because the finite size Δx_H of the hologram acts like a resolution-limiting aperture. The combination of Eqs. (13) and (14) yields

$$\Delta x_0 / \delta x_0 \leq \Delta x_H / D \quad (15)$$

This means that the number of image pixels $\Delta x_0 / \delta x_0$ is bounded by the number of CGH cells $\Delta x_H / D$. The generalization to two dimensions is straightforward. Again, Fourier CGH's benefit from the fact that the light propagation from the virtual object to the hologram plane can be described by a Fourier transformation. Hence, the FFT can be used.

And now we move to the synthesis of a Fresnel hologram. A Fresnel hologram is recorded at a finite distance z from the object. Hence, we have to simulate the wave propagation in free space from the object (at $z=0$) to the hologram at a distance z . This free space propagation can be described (in the paraxial approximation) as a convolution of object and quasi-spherical wave:

$$u_0(x) \rightarrow \int_{-\infty}^{\infty} u_0(x') \exp \left[\frac{-i\pi(x-x')^2}{\lambda z} \right] dx' = u(x, z) \quad (16)$$

In the Fourier domain the corresponding operation is:

$$\tilde{u}_0(\mu) \rightarrow \tilde{u}_0(\mu) \exp[-i\pi\lambda z \mu^2] = \tilde{u}(\mu, z) \quad (17)$$

The indirect execution of Eq. (16), based on Eq. (17), is easy: a Fourier transformation of the object converts $u_0(x)$ into $\tilde{u}_0(\mu)$, which is then multiplied by the quadratic phase factor, yielding $\tilde{u}(\mu, z)$. An inverse Fourier transformation produces $u(x, z)$. The two Fourier transformations consist typically of $4N \log N$ multiply/add operations. N is the number of pixels: image size Δx_0 , divided by the pixel size δx_0 . In the case of a rectangular object $u_0(x, y)$, the number of pixels is $\Delta x_0 \Delta y_0 / \delta x_0 \delta y_0$.

And now to the algorithmic effort for computing the convolution. The $u_0(x)$ has N pixels. And, the lateral size of the exponential is essentially $M = z / \delta z$, where δz means "depth of focus". The M describes the lateral size of the diffraction cone, measured in pixelsize units δx_0 . The convolution involves MN multiply/adds. A comparison of these two algorithms is dictated by the ratio

$$M / 4 \log N \quad (18)$$

The direct convolution is preferable if the distance z is fairly small. The integration limits of Eq. (16) depend on the oscillating phase $\pi x^2 / \lambda z$. Effectively, nothing is contributed to this integral, when this phase varies by more than 2π over the length, δx_0 , of an object pixel. Note that the pixel size of $u(x, z)$ does not change with the distance z , because the bandwidth $\Delta \mu(z) = \Delta \mu_0$ is z -independent. This is so because the power spectrum is z -invariant:

$$|\tilde{u}(\mu, z)|^2 = |\tilde{u}_0(\mu)|^2 \quad (19)$$

It is easy to proceed from here to the CGH synthesis of a 3-D object. One starts with an object detail $u_1(x)$ at z_1 , for example, a house as in Fig. 7. Then, one propagates to the next object detail at z_2 . This second detail may act as a multiplication (transmission) and as addition (source elements). This process is repeated as the wave moves towards the plane of the hologram. There, a reference wave has to be added just as in the Fourier case.

A very powerful algorithm for the CGH synthesis is iterative Fourier transform algorithm (IFTA) (Lesem *et al.*, 1969; Gerchberg and Saxton, 1972; Fienup, 1981). Suppose, we want to design a Fourier CGH, which looks like a person and whose reconstructed image shows the signature of that person (Fig. 8(A) and (B)). In other words, the two intensities

$$|u_H(x, y)|^2 \text{ and } |\tilde{u}_H(\mu, (v))|^2 \quad (20)$$

are determined. But, the phase distributions of u_H and $\tilde{u}_H$ are still at our disposal. The IFTA algorithm will yield those phases in many cases at the expense of ten, hundred or more Fourier transformations.

The IFTA algorithm is sometimes called "Fourier Ping-Ping" because it bounces back and forth between the (x, y) and the (μ, v) domain. The amplitudes $|u_H|$ and $|u_0|$ are enforced at every opportunity. But the associated phases are free to vary and to converge, eventually. If so, u_H and u_0 are completely known. The IFTA will not always converge, for example not if

$$|u_H(x, y)| = \delta(x, y) \text{ and } |\tilde{u}_H(\mu, (v))| = \delta(\mu, (v)) \quad (21)$$

Fig. 7 Synthesis of a hologram for a three-dimensional object.

Fig. 8 IFTA-CGH: (A) The Fourier CGH. (B) The optical reconstruction thereof. Courtesy of Bartelt, H.O.

But the chances are fairly good if both amplitudes are very often close to one and seldom near zero.

Finally, a few words about image holograms. An image plane CGH is trivial from an algorithmic point of view. The simulated propagation from object plane to image plane is usually an identity, apart from the finite bandwidth of the image forming system. Nevertheless, image plane holograms can be quite useful, for example for interferometric testing of a non-spherical mirror of an astronomical telescope (Hansler, 1968; McGovern and Wyant, 1971; Ichioka and Lohmann, 1972). The CGH is laid out to provide a wavefront that is suitable for an interferometric “null test”. The CGH serves as a “synthetic prototype”.

A fourth kind of CGH, to be named near-field CGH may emerge, perhaps. It operates in the near-field. And, it employs evanescent waves as they occur if object details are comparable in size with, or even smaller than, the wavelength. Conceivable topics are “super resolution” and “sub-lambda lithography”. Fundamentals and history of classical evanescent holography are reported in Bryngdahl (1973).

On Some Hardware Aspects

And now a few comments about the hardware aspects of the CGH’s. Remembering the CGH cells structure in Fig. 3(D) we saw the amplitude encoded as relative width W (Eq. (6)). Instead of the width one may use the relative height $H \leq 1$ as the amplitude parameter (Lohmann and Sinzinger, 1995). More efficient, but more difficult to manufacture are saw tooth shaped hologram cells (Brown and Lohmann, 1969). The saw tooth prism may be approximated by a phase stair, which is possible with today’s lithographic technology. The corresponding theory is called phase quantization (Goodman and Silvestri, 1970; Dallas, 1971).

Some CGH Applications

Optical Filtering

Some applications had been mentioned already before, for example, 3-D Display (see Fig. 7). The data volume can be very high. Hence, shortcuts such as eliminating the vertical perspective, are called for. The largest CGH’s for visual light are used for TESTING astronomical telescopes by means of interferometry. The IFTA algorithm has been used, among other things, for designing a CGH which acts as an optimal diffuser. Speckles and light efficiency are the critical issues in diffuser design. Another project that also benefits from IFTA is beam shaping. That is a broad topic with aims such as homogenizing the output of laser, beam structuring for welding (Dresel *et al.*, 1996), cutting, and scanning.

A CGH can also be used as a spatial filter for image processing. For example, an input image may be Hilbert-transformed in the setup shown in Fig. 9(A) (Hauk and Lohmann, 1958). The filter (Fig. 9(B)) is a grating, of which one sideband is shifted by one-half of the grating period. Such a geometric shift generates the π -phase shift that is needed for the Hilbert transformation. The same setup can be used also for implementing Zernike’s phase contrast (Lohmann and Paris, 1968). Now the grating is distorted such that the zero-frequency region at the optical axis is reduced in amplitude by (typically) a factor of 0.2. In addition, the phase is shifted by $\pi/2$ due to a fringe shift of a quarter period (Fig. 10(A)). In the image plane one can see an ordinary image on-axis, and two phase-contrast images in the plus-minus first diffraction orders. One of them has positive phase contrast, the other one has negative phase contrast (Fig. 10(B)). Another simple spatial filter (Fig. 11(A)) produces a derivative of the input $u(x,y)$: $\frac{\partial u(x,y)}{\partial x}$ (Fig. 11(B)). Eqs. (22)–(24) explain this differential filtering experiment.

$$u(x, y) \rightarrow \partial u(x, y) / \partial x = v(x, y) \quad (22)$$

$$\tilde{u}(\mu, (v)) \rightarrow 2\pi i \mu \cdot \tilde{u}(\mu, (v)) = \tilde{v}(\mu, (v)) \quad (23)$$

Fig. 9 (A) Hilbert setup. (B) Hilbert filter.

Fig. 10 (A) Phase contrast filter. (B) Phase contrast output.

Fig. 11 (A) Differentiation filter. (B) Differentiation output.

$$\tilde{p}(\mu, (v)) = 2\pi|\mu| \cdot \begin{cases} +i(\mu > 0) \\ -i(\mu < 0) \end{cases} \quad (24)$$

The phase portion of the filter (**Fig. 11(A)**) is the same as for the Hilbert filter. But, the filter amplitude now enhances the higher frequencies. The object used for getting the results of **Figs. 10(B)** and **11(B)** was a phase-only object: a bleached photograph.

A very famous spatial filtering experiment is “matched filtering” ([Vander Lugt, 1964](#); [Kozma and Kelly, 1965](#)). It can be used for pattern recognition. The original matched filters were classical Fourier holograms of the target pattern. Computer hologram's can do the same job ([Brown and Lohmann, 1966](#)), even with spatially incoherent objects ([Lohmann and Werlich, 1971](#)). Work on spectrally incoherent spatial filtering was initiated by [Katyl \(1972\)](#).

Fourier holograms are attractive also for data storage due to their robustness against local defects. A local error in the Fourier domain spreads out all over the image domain. The computed hologram has an advantage over classical holograms because of the freedom to incorporate any error detection and correction codes for reducing the bit error rate even further.

One of the most recent advances is in matched filtering with totally incoherent light ([Andrés et al., 1999](#); [Pe'er et al., 1999](#)). This step allows moving spatial filtering out of the well-guarded laboratory into hostile outdoor environments.

Optical Vortices

The mathematical key to understanding CGH generation of optical vortices ([Rozas et al., 1997](#)) is the circular harmonic. It is a function of two variables where θ is the angular member of the polar coordinate pair and n is the order of the harmonic. The

circular harmonic is

$$\exp(in\theta) \quad (25)$$

An optical wave at a plane with this complex amplitude $\exp(in\theta)$ is called an optical vortex with a topological charge of n . In order to design a CGH that converts a plane wave to an optical vortex the circular harmonic decomposition is used. Extending Eq. (2) to polar coordinates, the transmittance of the CGH is

$$T_H(r, \theta) = c_0 + c_1 \exp(in\theta) u_R^* + \dots \quad (26)$$

For a unit-amplitude normally-incident wave, the exiting optical vortex is numerically equal. The corresponding CGH mask is shown in Fig. 12.

These waves can be used, as propeller beams (Zhang *et al.*, 2010) that apply torque to components (cranks) of micro-mechanical devices. They can be used as optical traps (Ng *et al.*, 2010), for example, to trap Bose-Einstein condensates. They can also be employed in solar coronagraphs (Foo *et al.*, 2005).

Polarization CGH

Polarized light can be decomposed into two orthogonal components. For example, if the light is propagating in the z -direction, light in a plane can be decomposed into linearly polarized components: x -polarized and y -polarized. An arbitrarily polarized field can be composed by superimosing a field of x -polarized and a field of y -polarized light. This process is known as polarization synthesis (Lohmann, 1967; Noble *et al.*, 2010). An idealized synthesis process is illustrated in (Fig. 13) where two Fourier CGHs are inserted into a Mach-Zehnder interferometer. It combines the waves exiting both holograms into the arbitrarily-polarized reconstructed image.

Determining the strength of each component is known as polarization analysis. The generation steps for calculating the encoded waves of the CGHs are illustrated in the flow diagram of Fig. 14.

Fig. 12 Ninth-order vortex CGH.

Fig. 13 Polarized reconstruction.

Fig. 14 Flow diagram for straight-forward designing of a polarization CGH.

Terminology

Several terms mean more or less the same as CGH: synthetic hologram, digital hologram, holographic optical element (HOE), diffractive optical element (DOE) or digital optical element.

CGH's have been made also for other waves, such as acoustical waves, ocean waves, and microwaves. Digital antenna steering can be understood as a case of computer holography.

Introduction

One of the most fascinating properties of light is the fact that it encounters us both as a beam, as a wave, and as a particle. In the context of this article, however, we will only deal with the wave character of light and its sinusoidal nature. The accompanying ability of waves to interfere makes it possible to store spatial information on a two-dimensional target and to reconstruct the complete light field again. This is known as holography (Gabor, 1949). Even more, the superposition of waves and the precise knowledge of the wavelength guide us to a series of interesting methods for the high-resolution measurement of various physical quantities, such as three-dimensional distances, displacements, strains and refractive index distributions. The primary physical quantity of the wave field, which represents its three-dimensional properties, is the phase. Unfortunately, due to the high frequency of light, all media for the storage of light, whether photo-chemical (films, photoplates) or photo-electronic (CCD and CMOS detectors) can only register intensities. But the ability to interfere allows us to apply a trick: the interferometric principle. Simply by means of interferometry, phase changes are converted into measurable intensity changes. This is done in an interferometer where a primary wave front is divided into at least two wave trains, often called as object and reference wave, respectively, which are superimposed again after traveling along common or various paths. Finally, interferometry and holography enabled numerous outstanding applications such as the 3D-imaging of natural objects and scenes (Leith and Upatnieks, 1961; Denisjuk, 1962), the fabrication of diffractive optical elements (Lee, 1978), and the high-resolution inspection of static and dynamic objects having both precisely machined as well as rough surfaces (Steel, 1983; Powell and Stetson, 1965).

As already mentioned, the basic principle of holography consists in the transformation of phase changes into recordable intensity changes. Because of the high spatial frequency of these intensity fluctuations the registration of a hologram requires a light sensitive medium with adequate spatial resolution. Therefore, special photographic emulsions have dominated holographic technologies for a long period. However, the recording of holograms on electronic sensors and their numerical reconstruction is almost as old as holography itself. The first ideas and implementations were already conceived in the 1960s and 1970s (Goodman and Lawrence, 1967; Huang, 1971; Kronrod *et al.*, 1972; Demetrakopoulos and Mitra, 1974). But the most crucial step towards a practicable technology could only be made as digital cameras with reasonable space-bandwidth product and powerful processor technology became widely accessible. At the beginning of the 1990s these technical prerequisites were available and it was only a matter of time before they would be applied to the discrete recording, digital storage and numerical reconstruction of optical wave fronts, which is called digital holography. The article of Schnars and Jüptner from 1994 (Schnars and Jüptner, 1994) can be considered as a kind of initialization for a continuously growing number of implementations and applications. Meanwhile, digital holography has grown into a separate, distinct category in modern optics and has obvious implications in many fields such as microscopy (Yu *et al.*, 2014), 3D imaging (Frauel *et al.*, 2006), metrology (Kreis, 2005), display technology (Gang, 2013), material processing (Hasegawa *et al.*, 2006), data storage (Coufal *et al.*, 2000), and information processing (Yaroslavsky, 2004). A further remarkable extension of the application range of digital holography could be achieved by the application of sophisticated spatial light modulator (SLM) technology (Sutkowski and Kujawinska, 2000; Kohler *et al.*, 2006; Haist and Osten, 2015a,b), complementing the digital recording process with a matching digital optical reconstruction process. Since the late 1990s such devices have been offered by different companies (HOLOEYE Photonic AG; Lazarev *et al.*, 2012; HAMAMTSU Photonics K.K.) with the result that a bunch of new applications such as holographic micro-manipulation (Zwick *et al.*, 2010; Reichert *et al.*, 1999; Daneshpanah *et al.*, 2010), aberration compensation (Ferraro *et al.*, 2003; Liesener *et al.*, 2004), computational microscopy (Maurer *et al.*, 2010; Haist *et al.*, 2014; Marquet and Depeursinge, 2014; Kim, 2011), holographic displays (Onural *et al.*, 2011; Lee and Kim, 2012), comparative digital holography (Osten *et al.*, 2002; Baumbach *et al.*, 2006), and remote holographic laboratories (Osten *et al.*, 2013) could be implemented. Further recent application fields are described in (Osten *et al.*, 2014).

Meanwhile, modern digital holography is more than 25 years old. But it is still an equally young and dynamic discipline. Some emerging fields where digital holography in combination with modern photonic technologies shows their great potential for new applications in technical and living sciences are:

- the implementation of sophisticated illumination, imaging and reconstruction principles for the enhancement of the resolution of holographically stored images and for the reduction of the demands on the space-bandwidth product of holographic sensors,
- the combination of digital-holographic microscopy with SLM-based holographic 3D-micromanipulation for the in vivo investigation of living cells and tissues,
- the evaluation of the spatial coherence function measured by self-referenced interferometry with the objective to reduce the degree of coherence of the light needed for holographic storage and to derive spatial and spectral information about the objects under test,
- the application of modern light sources such as supercontinuum lasers and frequency combs for the high-precision depth mapping and 3D-reconstruction of objects and scenes,

- the iterative evaluation of the propagating wavefront for avoiding sensitive interferometric detection principles,
- the evaluation of light fields transmitted or reflected from strongly scattering or hidden objects, and
- the enabling of holographic procedures and setups for remote access and comparative inspection technologies.

Direct Phase Reconstruction by Digital Holography

In digital speckle pattern interferometry DSPI (Butters and Leendertz, 1971) the object is focused onto the target of an electronic sensor. Thus an image plane hologram is formed as result of the interference with an inline reference wave. In contrast with DSPI, a digital hologram can be recorded without imaging the object onto a target. The target records the superposition of the reference and the object wave in the near-field region – a so-called Fresnel hologram (Schnars and Jüptner, 1994). The basic optical setup in digital holography for recording holograms is the same as in conventional holography, Fig. 1(a). A laser beam is divided into 2 coherent beams. One beam illuminates the object and generates the object beam $u(x,y)$. The other enters the target directly and forms the reference wave $r(x,y)$. On this basis very compact solutions are possible. Fig. 1(b) shows a holographic camera where the interferometer, containing a beam splitter and some wave front shaping components, is mounted in front of the camera target. The object, drafted as a ball, is illuminated from four directions. This scheme has some advantages for the measurement of the shape and displacement of the object under test (see Section “The Fresnel approximation”).

For the description of the principle of digital Fresnel holography we use a simplified version of the optical setup, Fig. 2(a). The object is modeled by a plane rough surface that is located in the (x,y) -plane and illuminated by laser light. The scattered wave field forms the object wave $u(x,y)$. The target of an electronic sensor (e.g. a CCD or a CMOS) used for recording the hologram is located in the (ξ,η) -plane at the distance d from the object. Following the basic principles of holography (Gabor, 1949; Hariharan, 1984) the hologram $h(\xi,\eta)$ originates from the interference of the object wave $u(\xi,\eta)$ and the reference wave $r(\xi,\eta)$ in the (ξ,η) -plane:

$$h(\xi,\eta) = |u(\xi,\eta) + r(\xi,\eta)|^2 = r \cdot r^* + r \cdot u^* + u \cdot r^* + u \cdot u^* \quad (1)$$

The transformation of the intensity distribution $h(\xi,\eta)$ into a discrete and digital gray value distribution $T(m,n)$ that is stored in the image memory of the computer is considered by a characteristic function t of the sensor. This function is in general only approximately linear:

$$T(m,n) = t[h(\xi,\eta)] \quad (2)$$

Because the sensor has a limited spatial resolution the spatial frequencies of the interference fringes in the hologram plane – the so-called micro-interferences – have to be considered. The fringe spacing g in, for example, x -direction and the corresponding spatial frequency f_x , respectively, is determined by the angle β between the object and the reference wave, Fig. 2(b):

$$g = \frac{1}{f_x} = \frac{\lambda}{2\sin(\beta/2)} \quad (3)$$

with λ as the wavelength. If we assume that the discrete sensor has a pixel pitch (distance between two adjacent pixels) $\Delta\xi$ the sampling theorem requires at least 2 pixels per fringe for a correct reconstruction of the periodic function:

$$2\Delta\xi < \frac{1}{f_x} \quad (4)$$

Consequently, we obtain for small angles β :

$$\beta < \frac{\lambda}{2\Delta\xi} \quad (5)$$

Modern high-resolution CCD or CMOS chips have a pitch $\Delta\xi$ of about $4\mu\text{m}$. In that case a maximum angle between the reference and the object wave of only 4° is acceptable. The practical consequence of the restricted angle resolution in digital holography is a limitation of the effective object size that can be stored holographically by an electronic sensor. However, this is only a technical handicap. Larger objects can be placed in a sufficient distance from the hologram, or reduced optically by imaging with a negative lens.

The reconstruction is done by illumination the hologram with a so-called reconstruction wave $c(\xi,\eta)$:

$$u'(x',y') = t[h(\xi,\eta)] \cdot c(\xi,\eta) \quad (6)$$

The transmission function of the hologram $t[h(\xi,\eta)]$ (see Eq. (2)) diffracts the wave $c(\xi,\eta)$ in such a way, that images of the object wave are reconstructed. In general, four terms are reconstructed if the wave $u'(x',y')$ propagates in space. In case of a linear characteristic function $t(h) = \alpha h + t_0$ we can write:

$$u' = T \cdot c = t(h) \cdot c \quad (7)$$

and

$$u' = \alpha [cu^2 + cr^2 + cur^* + cru^*] + ct_0 \quad (8)$$

with two relevant image terms $[cur^*]$ and $[cru^*]$, containing the object wave u and its conjugated version u^* , respectively. The appearance of the image terms depends on the concrete shape of the reconstruction wave. In general, the original reference wave

(a) Schematic setup for recording a digital hologram onto a CCD target, (b) Implementation of a holographic camera by mounting a compact holographic interferometer in front of a CCD-target (four illumination directions are used). Osten, W., Seebacher, S., Jüptner, W. 2001. The application of digital holography for the inspection of micro-components. Proc. SPIE 4400, 1–15.

$c=r$ or its conjugated version $c=r^*$ is applied. In case of the conjugated reference wave a direct or real image will be reconstructed due to a converging image wave that can be imaged on a screen at the place of the original object.

However, in digital holography the reconstruction of the object wave in the image plane $u'(x',y')$ is done by numerical reproduction of the physical propagation process as shown in Fig. 3(a). The reconstruction wave, with a well-known shape equal to the reference wave $r(\xi,\eta)$, propagates through the hologram $h(\xi,\eta)$. Following the Huygens' principle each point $P(\xi,\eta)$ on the hologram acts as the origin of a spherical elementary wave. The intensity of these elementary waves is modulated by the transparency $h(\xi,\eta)$. In a given distance $d'=d$ from the hologram, a sharp real image of the object can be reconstructed as the superposition of all elementary waves. For the reconstruction of a virtual image, $d'=-d$ is used.

Consequently, the calculation of the wave field $u'(x',y')$ in the image plane starts with the pointwise multiplication of the stored and transformed intensity values $t[h(\xi,\eta)]$ with a numerical model of the reference wave $r(\xi,\eta)$. For a normally incident and

Fig. 3 Reconstruction of digital holograms. (a) Principle of wave front reconstruction, (b) light propagation by diffraction (Huygens-Fresnel principle).

monochromatic wave with unit amplitude, the reference wave can be modeled by $r(\xi, \eta)$. After the multiplication, the resulting field is propagated in free space with reference to the laws of e.g. nearfield diffraction. In the distance d' the diffracted field $u'(x', y')$ can be found by solving the well-known Rayleigh–Sommerfeld diffraction formula, which is also known as the Huygens–Fresnel principle (Goodman, 1996):

$$u'(x', y') = \frac{1}{i\lambda} \iint_{-\infty \dots \infty} t[h(\xi, \eta)] \cdot r(\xi, \eta) \frac{\exp(ik\rho)}{\rho} \cos\theta d\xi d\eta \quad (9)$$

with

$$\rho(\xi - x', \eta - y') = \sqrt{d'^2 + (\xi - x')^2 + (\eta - y')^2} \quad (10)$$

as the distance between a point $O'(x', y', z=d')$ in the image plane and a point $P(\xi, \eta, z=0)$ in the hologram plane and

$$k = \frac{2\pi}{\lambda} \quad (11)$$

as the wave number. The obliquity factor $\cos\theta$ represents the cosine of the angle between the outward normal and the vector joining P to O' . This term is given exactly by

$$\cos\theta = \frac{d'}{\rho} \quad (12)$$

and therefore Eq. (9) can be rewritten

$$u'(x', y') = \frac{d'}{i\lambda} \iint_{-\infty \dots \infty} t[h(\xi, \eta)] \cdot r(\xi, \eta) \frac{\exp(ik\rho)}{\rho^2} d\xi d\eta \quad (13)$$

The numerical reconstruction provides the complex amplitude of the wave front. Consequently, the phase distribution $\phi(x', y')$ and the intensity $I(x', y')$ can be calculated directly from the reconstructed complex function $u'(x', y')$:

$$\phi(x', y') = \arctan \frac{\text{Im}[u'(x', y')]}{\text{Re}[u'(x', y')]} \quad [-\pi, \pi] \quad (14)$$

$$I(x', y') = u'(x', y') \cdot u'^*(x', y') \quad (15)$$

The direct approach to the phase yields several advantages for imaging and metrology applications that are discussed later.

Reconstruction Principles in Digital Holography

The theoretical background for the reconstruction of digital holograms is given by the scalar diffraction theory. Based on this, different numerical reconstruction principles are applied: the Fresnel approximation (Schnars, 1994), the convolution approach (Demetrakopoulos and Mittra, 1974), the angular spectrum method (Goodman, 1996), the lens-less Fourier approach (Takeda *et al.*, 1996; Wagner *et al.*, 1999), the phase shifting approach (Yamaguchi and Zhang, 1979), and the phase-retrieval approach (Zhang *et al.*, 2003). In this section the main techniques are briefly described.

The Fresnel Approximation

If the distance d between the object and hologram plane, and equivalently $d' = d$ between the hologram and image plane, is large compared to $(\xi - x')$ and $(\eta - y')$, so that the Fresnel approximation is fulfilled, then the distance ρ^2 in the denominator of Eq. (13) can be replaced by d'^2 and the parameter ρ in the numerator can be approximated by a binomial expansion for the square root in Eq. (10) where only the first two terms are considered (Goodman, 1996):

$$\rho \approx d' \left[1 + \frac{(\xi - x')^2}{2d'^2} + \frac{(\eta - y')^2}{2d'^2} \right] \quad (16)$$

The resulting expression for the field at (x', y') becomes

$$u'(x', y') = \frac{\exp(ikd')}{i\lambda d'} \iint_{-\infty \dots \infty} t[h(\xi, \eta)] \cdot r(\xi, \eta) \exp \left[\frac{ik}{2d'} \{ (\xi - x')^2 + (\eta - y')^2 \} \right] d\xi d\eta \quad (17)$$

Eq. (17) is a convolution integral that can be expressed as

$$u'(x', y') = \iint_{-\infty \dots \infty} t[h(\xi, \eta)] \cdot r(\xi, \eta) H(\xi - x', \eta - y') d\xi d\eta \quad (18)$$

with the convolution kernel

$$H(x', y') = \frac{\exp(ikd')}{i\lambda d} \exp \left[\frac{ik}{2d} (x'^2 + y'^2) \right] \quad (19)$$

Another notation of Eq. (17) is found if the term $\exp\left[\frac{ik}{2d}(x'^2 + y'^2)\right]$ is taken out of the integral:

$$u'(x', y') = \frac{\exp(ikd')}{i\lambda d'} e^{i\frac{k}{2d'}(x'^2 + y'^2)} \iint_{-\infty \dots \infty} \left\{ t[h(\xi, \eta)] \cdot r(\xi, \eta) \cdot e^{i\frac{k}{2d'}(\xi^2 + \eta^2)} \right\} \exp\left[-i\frac{2\pi}{\lambda d'}(\xi x' + \eta y')\right] d\xi d\eta \quad (20)$$

or

$$u'(x', y') = \frac{\exp(ikd')}{i\lambda d'} e^{i\frac{k}{2d'}(x'^2 + y'^2)} \text{FT}_{\lambda d'} \left\{ t[h(\xi, \eta)] \cdot r(\xi, \eta) \cdot e^{i\frac{k}{2d'}(\xi^2 + \eta^2)} \right\} \quad (21)$$

where $\text{FT}_{\lambda d'}$ indicates the 2D-Fourier transform that has been modified by a factor $1/(\lambda d')$. Eq. (21) makes clear that the diffracted wave front u' results from the Fourier transform FT of the digitally stored hologram $t[h(\xi, \eta)]$ multiplied by the reference wave, $r(\xi, \eta)$, and a quadratic phase factor, the so-called the chirp function $\exp\left\{i\frac{k}{2d'}(\xi^2 + \eta^2)\right\}$. This Fourier transform is scaled by the constant factor $1/(i\lambda d')$ and a phase factor that is independent of the processed hologram.

The discrete sampling in digital holography with the discrete pixel coordinates (m, n) requires the transformation of the infinite continuous integral in Eq. (20) into a finite discrete sum. This results in the finite Fresnel transform:

$$u'(m, n) = \sum_{j=0}^{M-1} \sum_{l=0}^{N-1} t[h(j \cdot \Delta\xi, l \cdot \Delta\eta)] \cdot r(j \cdot \Delta\xi, l \cdot \Delta\eta) \exp\left[\frac{i\pi}{d'\lambda} (j^2 \Delta\xi^2 + l^2 \Delta\eta^2)\right] \times \exp\left\{-i2\pi\left(\frac{j \cdot m}{M} + \frac{l \cdot n}{N}\right)\right\} \quad (22)$$

where constants and pure phase factors preceding the sums have been omitted. The main parameters are the pixel number $M \times N$ and the pixel pitches $\Delta\xi$ and $\Delta\eta$ in the two directions which are defined by the used sensor chip.

The discrete phase distribution $\phi(m, n)$ of the wave front and the discrete intensity distribution $I(m, n)$ on the rectangular grid of $M \times N$ sample points can be calculated from the reconstructed complex function $u'(m, n)$ by using Eqs. (14) and (15), respectively. The wrapped phase distribution is computed directly without the need of additional temporal or spatial phase modulation like phase shifting or spatial heterodyning (Creath, 1993; Kujawinska, 1993). Fig. 4 shows the result of the numerical reconstruction of the intensity and the phase of a tin soldier using a setup of the kind shown in Fig. 1(a).

Fig. 4 (a) Tin soldier, (b) digital hologram, (c) Reconstructed Intensity $I(m, n)$, (d) Reconstructed phase distribution $\phi(m, n)$.

For interferometric applications with respect to displacement and shape measurement (Kreis, 2005; Osten and Ferraro, 2007) the phase difference $\delta(m, n)$ of the two reconstructed wave fields $u_1'(m, n)$ and $u_2'(m, n)$ corresponding to the two states of the object needs to be calculated. The algorithm can be reduced to the following equation:

$$\delta(m, n) = \phi_1(m, n) - \phi_2(m, n) \quad (23)$$

Fig. 5 shows the principle of displacement measurement by digital holography. Besides the investigation of surface displacements in the region of the wavelength, digital holography can be applied advantageously for the measurement of the shape of complex objects. In Fig. 6 a turbine blade was investigated with the 2-wavelength contouring method (Osten *et al.*, 1998). Both, the digitally reconstructed mod 2π -phase and its demodulated version after phase unwrapping are presented (Wagner *et al.*, 2000). Phase unwrapping is necessary in digital holography since the fringe-counting problem still remains. However, there are some efficient approaches to overcome the difficulties of that process (Wagner *et al.*, 2000; Osten and Kujawinska, 2000).

Following Eq. (22), the pixel sizes in the reconstructed image along the two directions are

$$\Delta m = \frac{d'\lambda}{M\Delta\xi} \text{ and } \Delta n = \frac{d'\lambda}{N\Delta\eta} \quad (24)$$

In addition to the real image, a blurred virtual image and a bright dc-term, the zero-order diffracted field, are reconstructed. The dc-term can effectively be eliminated by preprocessing the stored hologram (Kreis and Jüptner, 1997; Seebacher *et al.*, 1997), and the different terms can be separated by using the off-axis instead of the in-line scheme. However, the spatial separation between the object and the reference field requires a sufficient space-bandwidth product of the used CCD-chip, as discussed in the section on direct phase reconstruction above.

Numerical Reconstruction by the Convolution Approach

In Section "The Fresnel approximation" we have already mentioned that the connection between the image term $u'(x', y')$ and the product $t[h(\xi, \eta)] \cdot r(\xi, \eta)$ can be described by a linear space-invariant system. The diffraction formula (17) is a superposition integral with the impulse response

$$H(x' - \xi, y' - \eta) = \frac{\exp(ikd')}{i\lambda d'} \exp\left[\frac{ik}{2d'} \left\{(\xi - x')^2 + (\eta - y')^2\right\}\right] \quad (25)$$

A linear space-invariant system is characterized by a transfer function G that can be calculated as the Fourier-transform of the impulse response:

$$G(f_x, f_y) = \text{FT}\{H(\xi, \eta, x', y')\} \quad (26)$$

with the spatial frequencies f_x and f_y . Consequently, the convolution theorem can be applied, which states that the Fourier transform of the convolution $t[h(\xi, \eta)] \cdot r(\xi, \eta)$ with H is the product of the individual Fourier transforms $\text{FT}\{t[h(\xi, \eta)] \cdot r(\xi, \eta)\}$ and $\text{FT}\{H\}$. Thus $u'(x', y')$ can be calculated by the inverse Fourier transform of the product of the Fourier-transformed convolution partners:

$$u'(x', y') = \text{FT}^{-1}\{\text{FT}[t(h) \cdot r] \cdot \text{FT}[H]\} \quad (27)$$

$$u'(x', y') = [t(h) \cdot r] \otimes H \quad (28)$$

Fig. 5 The principle of digital holographic interferometry demonstrated on example of a loaded small beam. The interference phase is the result of the subtraction of the two phases which correspond to the digital holograms of the both object states.

Fig. 6 Phase reconstruction by digital holographic interferometry on example of 2-wavelength contouring of a turbine blade. (a) image of the turbine blade, (b) mod-2 π phase distribution, (c) unwrapped phase distribution, (d) CAD reconstruction of the turbine blade.

with $\otimes$ as the convolution symbol. The computing effort is comparatively high: two complex multiplications and three Fourier transforms. The essential difference compared to the Fresnel approximation is the different pixel size in the reconstructed field (Kreis, 2005). The pixel size is constant independent from the reconstruction distance d' , wavelength λ and pixel number m :

$$\Delta x' = \Delta \xi \text{ and } \Delta y' = \Delta \eta \quad (29)$$

Numerical Reconstruction by the Lensless Fourier Approach

We have already mentioned that the limited spatial resolution of the sensor restricts the angular resolution of the digital hologram. In fact, the sampling theorem requires that the angle between the object beam and the reference beam at any point of the electronic sensor be limited in such a way that the microinterference spacing is larger than double the pixel size. In general, the angle between the reference beam and the object beam varies over the sensor's surface, and so does the maximum spatial frequency. Thus for most holographic setups the full spatial bandwidth of the sensor cannot be used. However, it is very important to use the entire spatial bandwidth of the sensor because the lateral resolution of the reconstructed image depends on a complete evaluation of all the information one can get from the sensor.

Fig. 7 Scheme of a setup for digital lensless Fourier holography of diffusely reflecting objects.

Even if the speed of digital signal processing is increasing rapidly, algorithms should be as simple and as fast to compute as possible. For the Fresnel approach and the convolution approach several fast Fourier transforms and complex multiplications are necessary. Therefore a more effective approach such as the subsequently described algorithm seems promising.

The lensless Fourier approach (Takeda *et al.*, 1996; Wagner *et al.*, 1999) is the fastest and most suitable algorithm for small objects. The corresponding setup is shown in Fig. 7. It allows us to choose the lateral resolution in a range from a few microns to hundreds of microns without any additional optics. Each point (ξ, η) on the hologram is again considered as a source point of a spherical elementary wave front (Huygen's principle). The intensity of these elementary waves is modulated by $t[h(\xi, \eta)]$ – the amplitude transmission of the hologram. The reconstruction algorithm for lensless Fourier holography is based on the Fresnel reconstruction. Here, again $u(x, y)$ is the object wave in the object plane, $h(\xi, \eta)$ the hologram, $r(\xi, \eta)$ the reference wave in the hologram plane and $u'(x', y')$ the reconstructed wave field.

For the specific setup of lensless Fourier holography a spherical reference wave is used with an origin in the same distance from the sensor as the object itself. In the case that $d' = -d$, $x = x'$, and $y = y'$ both virtual images are reconstructed and the reconstruction algorithm is then

$$u'(x', y') = \frac{\exp(ikd)}{i\lambda d} e^{-i\frac{k}{2d}(x^2 + y^2)} \text{FT}_{\lambda d} \left\{ t[h(\xi, \eta)] \cdot r(\xi, \eta) \cdot e^{-i\frac{k}{2d}(\xi^2 + \eta^2)} \right\} \quad (30)$$

where $\text{FT}_{\lambda d}$ is the two-dimensional Fourier transformation which has been scaled by a factor $1/(\lambda d)$. In this recording configuration, the effect of the spherical phase factor associated with the Fresnel diffraction pattern of the object is eliminated by the use of a spherical reference wave $r(\xi, \eta)$ with the same average curvature:

$$r(x, y) = \text{const} \cdot \exp\left(i\frac{\pi}{\lambda d}(\xi^2 + \eta^2)\right) \quad (32)$$

This results in a more simple reconstruction algorithm which can be described by

$$u'(x', y') = \text{const} \cdot \exp\left(-i\frac{\pi}{\lambda d}(x^2 + y^2)\right) \text{FT}_{\lambda d} \{h(\xi, \eta)\} \quad (33)$$

Besides the faster reconstruction algorithm (only one Fourier transform has to be computed), the Fourier algorithm uses the full space-bandwidth product (SBP) of the sensor chip because it adapts the curvature of the reference wave to the curvature of the object wave.

Influences of Discretization

For the estimation of the lateral resolution in digital holography three different effects related to discretization have to be considered (Wagner *et al.*, 1999): averaging, sampling and the limited sensor size. We assume a quadratic sensor with $N \times M$ pixels of size $\Delta\xi \times \Delta\eta$. Each pixel has a light sensitive region with a side length $\gamma\Delta\xi = \Delta\xi_{\text{eff}}$. The quantity γ^2 is the so-called fill factor ($0 \leq \gamma \leq 1$) that indicates the active area of the pixel. The sensor averages the incident light which has to be considered because of

possible intensity fluctuations over this area. The continuous expression for the intensity $I(\xi, \eta) = t[h(\xi, \eta)]$ registered by the sensor has to be integrated over the light sensitive area. This can be expressed mathematically by the convolution of the incident intensity $I(\xi, \eta)$ with a rectangle function (Goodman, 1996)

$$I^1(\xi, \eta) \propto I \otimes \text{rect}_{\Delta\xi_{\text{eff}}, \Delta\eta_{\text{eff}}} \quad (34)$$

The discrete sampling of the light field is modeled by the multiplication of the continuous assumed hologram with the two-dimensional comb-function:

$$I^2(\xi, \eta) \propto I^1(\xi, \eta) \cdot \text{comb}_{\Delta\xi, \Delta\eta} \quad (35)$$

Finally, the limited sensor size requires that the comb-function has to be truncated at the borders of the sensor. This is considered by the multiplication with a two-dimensional rect-function of the size $N_x \Delta\xi$:

$$I^3(\xi, \eta) \propto I^2 \cdot \text{rect}_{N\Delta\xi, N\Delta\eta} \quad (36)$$

The consequences are amplitude distortion, aliasing and speckling that have to be considered in the reconstruction procedure (Wagner *et al.*, 1999; Seebacher, 2001).

Advantages of Digital Holography

Besides the electronic processing and the direct access to the phase some further advantages recommend digital holography for several applications such as metrology and microscopy (Osten, 2003).

- The availability of the independently reconstructed phase distributions of each individual state of the object and interferometer, respectively, offers the possibility to record a series of digital holograms with increased load amplitude. In the evaluation process the convenient states can be compared interferometrically. Furthermore, a series of digital holograms with increasing load can be applied to unwrap the $\text{mod } 2\pi$ -phase temporally (Wagner *et al.*, 2000). In this method the total object deformation is subdivided in many measurement steps in which the phase differences are smaller than 2π . By adding up those intermediate results, the total phase change can be obtained without any further unwrapping. This is an important feature, since it is essential to have an unwrapped phase to be able to calculate the real deformation data from the phase map. Fig. 8 shows an example of such a measurement. The left image shows the wrapped deformation phase for a clamped coin which was loaded with heat. The right image shows the temporal unwrapped phase which has been obtained by dividing the total deformation into 85 sub-measurements. Thus the displacement of the object can be observed almost in real time during the loading process.
- The independent recording and reconstruction of all states gives also a new degree of freedom for optical shape measurement. In case of multi-wavelength contouring each hologram can be stored and reconstructed independently with its corresponding wavelength. This results in a significant decrease of aberrations and makes it possible to use larger wavelength differences for the generation of shorter synthetic wavelengths (Wagner *et al.*, 2000).
- Because all states of the inspected object can be stored and evaluated independently, only seven digital holograms are necessary to measure the 3D-displacement field and – shape of an object under test: one holograms for each illumination direction before and after the loading, respectively, and one hologram with a different wavelength (or a different source-point of illumination) which can interfere with one of the other holograms to do two-wavelength-contouring (or two-source-point-contouring) for shape measurement. If four illumination directions are used nine holograms are necessary (Seebacher *et al.*, 2001).
- The direct approach to the phase enables various new microscopic principles for the investigation of phase objects. They are categorized with the term Quantitative Phase Contrast Microscopy (Cuche *et al.*, 1999; Kim, 2011).

Fig. 8 Temporal unwrapping by digital holography. (a) wrapped phase of a thermal loaded coin, (b) temporally unwrapped phase.

- Digital holography also allows new approaches for the exploration and exploitation of scattering media (Singh *et al.*, 2017).
- Last but not least, the complex holographic sensor setups can be miniaturized drastically (Kolenovic *et al.*, 2003) and methods for remote comparative interferometry (Baumbach *et al.*, 2006) make digital holography to a versatile tool for the solution of numerous future inspection and measurement problems.

Major Milestones

- 1948: Essential concept for holographic recording by Dennis Gabor.
- 1960: The first successful operation of a laser device by Theodore Maiman.
- 1962: Off-axis technique of holography by Leith and Upatnieks.
- 1962: Yu N Denisjuk suggested the idea of three-dimensional holograms based on thick photoemulsion layers. His holograms can be reconstructed in ordinary sunlight. These holograms are called Lippmann–Bragg holograms.
- 1964: Leith and Upatnieks pointed out that a multicolor image can be produced by a hologram recorded with three suitably chosen wavelengths.
- 1969: S A Benton invented 'Rainbow Holography' for display of holograms in white light. This was a vital step to make holography suitable for display applications.

Holography is the science of recording an entire optical wavefront, both amplitude and phase information, on appropriate recording material. The record is called a hologram. Unlike conventional photography, which records a three-dimensional scene in a two-dimensional format, holography records true three-dimensional information about the scene.

Holography was invented by Gabor in 1948 and his first paper introduced the essential concept for holographic recording – the reference beam. Holography is based on the interference between waves and, it provides us with a way of storing all the light information arriving at the film in such a way that it can be regenerated later.

The use of the reference beam is utilized because the physical detectors and recorders are sensitive only to light intensity. The phase is not recorded but is manifest only when two coherent waves of the same frequency are simultaneously present at the same location. In that case, the waves combine to form a single wave whose intensity depends not only on intensities of the two individual waves, but also on the phase difference between them. This is key to holography. The film record, or hologram, can be considered as a complicated diffraction grating. Holograms bear no resemblance to conventional photographs in that an image is not actually recorded. In fact, the interferometric fringes which are recorded on the recording material are not visible to an unaided eye because of extremely fine interfringe spacing (~ 0.5 micrometer). The fringes which are visible on the recording material are the result of dust particles in the optical system used to produce the hologram.

Gabor's original technique is now known as in-line holography. In this arrangement, the coherent light source as well as the object, which is a transparency containing small opaque details on a clear background, is located along the axis normal to the photographic plate. With such a system, an observer focusing on one image observes it superposed on the out-of-focus twin image as well as a strong coherent background. This constitutes the most serious problem of Gabor's original technique.

The first successful technique for separating the twin images was developed by Leith and Upatnieks in 1962. This is called the off-axis or side band technique of holography. We shall consider mainly the off-axis technique here.

Basic Holography Principle

Light from a laser or any light beam is characterized by spatial coherence (l_c) and temporal coherence (τ_c), which is discussed in all textbooks on optics. For typical laboratory hologram recording, the required degree of coherence of laser radiation is determined by the type of object and geometrical arrangement being used for the recording. The following condition must hold:

$$L \ll c\tau_c \quad (1)$$

where τ_c is the coherence time, and L the maximum path length difference between the two waves chosen to record the hologram. To begin recording, two wavefronts are derived from the same laser source. One wavefront is used to illuminate the object and another is used as a reference wavefront. The wavefront derived by illuminating the object is superimposed with the reference wave and the interference pattern is recorded. These object and reference waves must:

- be coherent (derived from the same laser); and
- have a fixed relative phase at each point on the recording medium.

If the above conditions are not met, the fringes will move during the exposure and the holographic record will be smeared. Therefore, to record the hologram one should avoid air currents and vibrations. The recording medium must have sufficient resolution to record the fine details in the fringe pattern. This will be typically of the order of the wavelength. To create a three-dimensional image from the holographic process one then has to record and reconstruct the hologram. The object and reference waves are derived from the same laser.

Holograms record an interference pattern formed by interference of object and reference wavefronts, as explained above. We may mention here that for the two plane waves propagating at an angle θ between them, the spacing of the interference fringes is given by

$$\alpha = \frac{\lambda_0}{2 \sin(\theta/2)} \quad (2)$$

where λ_0 is the free space wavelength.

Processing of the hologram (developing, fixing, and washing of the recording material) yields a plate with alternating transparent and opaque parts, variation of refractive index, or variation of height corresponding to intensity variation in the fringe pattern. Such a plate can be regarded as a complicated diffraction grating. In this process, the hologram is illuminated with monochromatic, coherent light. The hologram diffracts this light into wavefronts which are essentially indistinguishable from the original waves which were diffracted from the object. These diffracted waves produce all the optical phenomena that can be produced by the original waves. They can be collected by a lens and brought into focus, thereby forming an image of the original object, even though the object has since been removed. If the reconstructed waves are intercepted by the eye of an observer, the effect is exactly as if the original waves were being observed; the observer sees what appears to be the original object in true three-dimensional form. As the observer changes his viewing position, the perspective of the image scene changes; parallax effects are evident and the observer must refocus when the observation point is changed from a near to a distant object in the scene. Assuming that both the construction and reconstruction of the hologram are made with the same monochromatic light source, there is no visual test which can be made to distinguish between the real object and the reconstructed image of the object. It is as if the hologram were a window through which the apparent object is viewed.

Hologram of a Point Object

Consider a hologram recorded with a collimated reference wave normal to the recording plate and a point object inclined at a certain angle. If the hologram is illuminated once again with the same collimated reference wave, it reconstructs two images, one virtual true image and the other real image. However, the two images differ in one very important respect.

While the virtual image is located in the same position as the object and exhibits the same parallax properties, the real image is formed at the same distance from the hologram but in front of it. Corresponding points on the real and virtual images are located at equal distances from the plane of the hologram; the real image has the curious property that its depth is inverted. Such an image is not formed with a normal optical system; it is therefore called a pseudo image as opposed to a normal or orthoscopic image.

This depth inversion results in conflicting visual clues, which make viewing of the real image psychologically unsatisfactory. Thus, if O_1 and O_2 are two elements in the object field, and if O_1 blocks the light scattered by O_2 at a certain angle, the hologram records information only on the element O_1 at this angle and records no information about this part of O_2 . An observer viewing the real image from the corresponding direction then cannot see this part of O_2 , which, contrary to normal experience, is obscured by O_1 , even though O_2 is in front of O_1 .

Production of an Orthoscopic Real Image

An orthoscopic real image of an object can be produced by recording two holograms in succession. In the first step, a hologram is recorded of the object with a collimated reference beam. When this hologram is illuminated once again with the collimated reference beam that was used to record it, it reconstructs two images of the object at unit magnification, one of them being an orthoscopic virtual image, while the other is a pseudoscopic real image. A second hologram is then recorded of this real image with a second collimated reference beam.

When the second hologram is illuminated with a collimated beam it reconstructs a pseudoscopic virtual image located in the same position as the real image formed by the second hologram is an orthoscopic image. Since a collimated reference beam is used throughout, the final real image is the same size as the original object and free from aberrations.

In addition to these characteristic linked intensities with the three-dimensional nature of the reconstruction, the holographic recording has several other properties. Each portion of the hologram can reproduce the entire image scene. If a smaller and smaller portion of the hologram is used for reconstruction, there is loss of image intensity and reconstruction. When a hologram is reversed, such as in contact printing processes, it will still reconstruct a positive image indistinguishable from the image produced by the original hologram.

Simple Mathematical Description of Holography

Let the object and reference waves be given by

$$U_o = O(x, y)e^{i\phi(x, y)} \quad (3)$$

and

$$U_r = R e^{iky \sin \theta} \quad (4)$$

U_r describes the reference (plane wave) propagating at angle θ to the z -axis.

The intensity at the hologram plane is

$$\begin{aligned} I &= |U_r + U_o|^2 \\ &= |U_r|^2 + |U_o|^2 + U_r^* U_o + U_r U_o^* \end{aligned} \quad (5)$$

As can be seen from the above equation, the amplitude and phase of the wave are encoded as the amplitude and phase modulation of a set of interference fringes. The material used to record the patterns of interference fringes described above is assumed to provide linear mapping of the intensity incident during the reconstruction process into amplitude transmitted by or reflected from the recorded material. Usually both light detection and wavefront modulation are performed by photographic plate/film. We assume the amplitude transmission properties of the plate/film after processing to be described by

$$T = T_o - b(E - E_o) \quad (6)$$

where the exposure E , at the film is $E = I\tau$; here τ is the exposure time. T_o is the transmittance of the unexposed plate.

If the hologram is reilluminated by the reference wave, the transmitted wave amplitude will be

$$U_t = U_r(T_o - b\tau(|U_o|^2 + U_r^* U_o + U_r U_o^*)) \quad (7)$$

The first term is reference wave times a constant. The second term is the reference wave modulated by $|U_o|^2 = O(x, y)^2$; it gives small-angle scattering about the reference wave direction. The third term is proportional to U_o . It is the same as the original object wave (note this is only so if the reconstruction wave is identical to the reference wave). The fourth term is

$$-b\tau U_r^2 U_o^* = -b\tau R^2 e^{iky 2 \sin \theta} O(x, y) e^{-i\phi(x, y)} \quad (8)$$

This is essentially a wave traveling in a direction $\sin^{-1}(2 \sin \theta)$ to the z -axis, with the correct object amplitude modulation but its phase reversed in sign, producing a conjugate wave.

Types of Holograms

Primarily, the holograms are classified as thin and thick, based on the thickness of the recording medium. When the thickness of the recording medium is small compared with the average spacing of the interference fringes, the hologram can be treated as a thin hologram. Such holograms are characterized by spatially varying complex amplitude transmittance:

$$t(x, y) = [t(x, y)] \exp[-i\phi(x, y)] \quad (9)$$

Thin holograms can be further categorized as thin amplitude holograms or thin phase holograms. If amplitude transmittance of the hologram is such that $\phi(x, y)$ is constant while $t(x, y)$ varies over the hologram, the hologram is termed an amplitude hologram. For a lossless phase hologram, $|t(x, y)| = 1$, so that the complex amplitude transmittance is caused by variation in phase.

When the thickness of the hologram recording material is large compared to the fringe spacing of the interference fringes, the holograms may be considered as volume holograms. These may be treated as a three-dimensional system of layers corresponding to a periodic variation of absorption coefficient or refractive index, and the diffracted amplitude is at a maximum when Bragg's condition is satisfied. In general, the behavior of thin and thick holograms corresponds to Raman Nath and Bragg diffraction regimes. The distinctions between two regimes is made on the basis of a parameter Q , which is defined by the relation:

$$Q = \frac{2\pi\lambda_o d}{n_o \Lambda^2} \quad (10)$$

where

Λ = spacing of fringe on hologram, measured normal to the surface;

d = thickness of recording medium;

n_o = mean refractive index of the medium; and

λ_o = wavelength of light.

Small values of Q ($Q < 1$) correspond to thin gratings, while large values of Q ($Q > 10$) correspond to volume gratings. For values of Q between 1 and 10, intermediate properties are exhibited. However, this criterion is not always adequate. The boundaries between the thin and thick holograms are given by the value of

$$P = \frac{\lambda_o^2}{\Lambda^2 n_o n_1} \quad (11)$$

where P^{-2} is the relative power diffracted into higher orders, and $P < 1$ for thin holograms and $P > 10$ for thick holograms. For P having values between 1 and 10, the hologram may be thin or thick, depending on the other parameters involved.

Holograms can also be classified based on whether they are reconstructed in transmitted light or reflected light. For transmission holograms, during the recording stage, two interfering wavefronts make equal but opposite angles to the surfaces of

recording medium and are incident on it from the same side. Reflection holograms reconstruct images in reflected light. They are recorded such that the interfering wavefronts are symmetrical with respect to the surface of the recording medium but are incident on it from opposite sides. When the angle between the interfering wavefronts is maximum (180°), the spacing between the fringe planes of the recording medium is minimum. Under such conditions, reflection holograms may have wavelength sensitivity high enough to be reconstructed, even with white light.

An important development in the field of holography was the invention of rainbow holograms by Benton in 1969. This provides a method for utilizing white light for illumination when viewing the holograms. The technique does so by minimizing the blur introduced by color dispersion in transmission holograms, at the price of giving up parallax information in one dimension.

Recording Materials

An ideal recording medium for holography should have a well matching spectral sensitivity corresponding to available laser wavelengths, linear transfer characteristics, high resolution, and low noise. It should also be either inexpensive or indefinitely recyclable. Toward achieving the above-mentioned properties, several materials have been studied, but none has been found so far that meets all the requirements. Materials investigated include: silver halide photographic emulsion; dichromated gelatin plates/films; silver halide sensitized gelatin plates/films; photo-resists; photo polymer systems; photochromics; photo thermoplastics; and ferro-electric crystals. Recently, the use of storage and processing capabilities of computers, together with CCD cameras, has been used for recording holograms.

Silver halide photographic emulsions are a commonly used recording material for holography, mainly because of relatively high sensitivity and easy availability. Manufacture, use, and processing of these emulsions have been well standardized. The need for wet processing and drying may constitute a major drawback. Dichromated gelatin can be considered an almost ideal recording material for volume phase holograms, as it has a large refractive index modulation capability, high resolution, low absorption and scattering.

Because of these features, dichromated gelatin has been extensively investigated. The most significant disadvantage is its comparatively low sensitivity. Pennington *et al.* developed an alternative technique, which combines the advantage of silver halide emulsions (high sensitivity) with that of dichromated gelatin (low absorption scattering and high stability). It involves exposing silver halide photographic emulsion and then processing it, so as to obtain a volume phase hologram consisting solely of hardened gelatin.

Thin phase holograms can be recorded on photoresists, which are light-sensitive organic films yielding relief image after exposure and development. They offer advantages of easy replication using thermoplastics but are slow in response and undergo nonlinear effects at diffraction efficiency greater than ~ 0.05 . Shipley AZ-1350 is a widely used photoresist, with maximum sensitivity in the ultraviolet, dropping rapidly for longer wavelengths towards the blue.

Photopolymers are being keenly investigated because they offer advantages such as ease of handling, low cost, and real-time recording for the application of holography and nonlinear optics. However, they have low sensitivity and short shelf life.

Thin phase surface relief holograms can be recorded in a thin layer of thermoplastics. These materials have a reasonably high sensitivity over the whole visible spectrum, fairly high diffraction efficiency, and do not require wet processing. Their application in holographic interferometry, optical information processing, and in making compact holographic devices has been widely reported.

Photorefractive crystals such as $\text{Bi}_{12}\text{SiO}_{20}$, LiNbO_3 , $\text{Bi}_{12}\text{GeO}_{20}$, BaTiO_3 , LiTaO_3 , etc., as recording materials, offer high-angular sensitivity and provide capability to read and write volume holographic data in real time. Besides the materials discussed here, several other materials have been investigated for recording holograms; these include photocromics, elastomere devices, magneto-optic materials, etc.

Application of Holography

Holography can be constructed not only with the light waves of lasers, but also with sound waves, microwaves, and other waves in the electromagnetic spectrum of radiation. Holograms made with ultraviolet light or X-rays can record images of objects/particles smaller than the wavelength of visible light, e.g., atoms or molecules. Acoustical holography uses sound waves to see through solid objects. Holography has a vast scope of practical applications, which have been classified into two major categories:

1. applications requiring three-dimensional images for visual perception; and
2. applications in which holography is used as a measuring tool.

The unique ability of holography – to record and reconstruct both electromagnetic and sound waves – makes it a valuable tool for education, science, industry, and business. Below are some of the important applications:

1. Holographic interferometry (HI) is one of the most powerful measuring tools. In HI, two states of an object, i.e., initial and deformed state are recorded on the same photographic plate. After reconstruction of the light wave corresponding to two states of an object, interferences and deformations are displayed in terms of the interference pattern. The change of distance of one tenth of a micron, or lower, can be resolved. HI provides scientists/engineers with crucial data for design of critical machine

parts of power-generating equipment, in the aircraft industry, automobile industry, and nuclear installations (say, for example, in the design of containers used to transport nuclear materials, improve the design of aircraft wings and turbine blades, etc.). Presently, HI is being widely used in mechanical engineering, acoustics, and aerodynamics, for nondestructive testing, to investigate oscillation in diaphragms and flow around various objects, respectively.

2. Microwave holography can detect objects deep within spaces, by recording the radio waves they emit.
3. Another important application of holography is the design of optical elements, which possess special properties. A holographic recording of a concave mirror behaves in much the same way as the mirror itself, i.e., it can focus the light. In some cases chromatism can be introduced in the design of elements so that a location of the point, where the beams are focused, depends on the wavelength. This can be achieved by accurately choosing the recording arrangement of the focusing elements, these elements are, in fact, diffraction gratings. These can have low noise levels, freedom from astigmatism, and have other useful properties. Holographic optical elements have found applications in supermarket scanners to read barcodes, headup displays in fighter aircraft to observe critical cockpit instruments, etc.
4. A telephone credit card used in Europe and other developed countries has embossed surface holograms which carry a monetary value. When the card is inserted into the telephone, a card reader discerns the amount due and deducts the appropriate amount to cover the cost of the call.
5. Holography is having applications in analog and digital computers, offering remarkable opportunities to realize various logical operators, devices for identifying images based on matched filtering, and in computer memory units. The basic advantage of holographic memory is that a relatively large volume of information can be stored and that there are a limited number of ways to change the record. The arrival of the first prototype of optical computers, which use holograms as storage material for data, could have a dramatic impact on the holographic market. The yet-to-be-unveiled optical computers will be able to deliver trillions of bits of information faster than the current generation of computers.
6. Optical tweezers are going to become an important tool for the study of micro-organisms/bacteria, etc.
7. Holograms can be used to locate and retrieve information without knowing its location in the storage medium, only needing to know some of its content.
8. The links between computer science and holography are now well-established and are developing, with at least two aspects making computer-generated holograms extremely interesting. First, such holograms enable us to obtain visual 3-dimensional reconstructions of imagined objects. For example, one can reconstruct three dimensions of a model of an object still in the design stage. Second, computer-generated holograms can be used to reconstruct lightwaves with specified wave fronts. This means specially computed and manufactured holograms may function as optical elements that transform the incident light wave into desired wavefronts.
9. Another important applications of holography is its utilization to compensate for the distortion that occurs when viewing objects through optically heterogeneous mediums. It can be achieved based on the principle of beam reversal by the hologram.
10. Finally, let us consider the application of holography to art. The development of holography gives very effective ways of creating qualitative three-dimensional images. Thus, a new independent area of holographic creative work representational/artistic holography has appeared. The art of holographic depiction has developed along two major routes. The first is creation of the view hologram, used as holograms of natural objects that are to be displayed in exhibitions and museums; these are also known as artistic holograms. Portrait holography is also classified under this category. The progress in portrait holography is hampered partly because of imperfection of pulsed lasers and partly because of the deterioration of photographic material when exposed to pulsed electromagnetic radiation.

The principle behind the creation of elusion by using composite holograms is also very convincing for the display of objects. To synthesize the composite holograms, the photographs of various aspects of a scene are printed onto the photographic plate. The synthesis techniques for preparing the composite hologram are very complicated, while the images created by holograms are still far from perfect. However, there is no doubt that composite holography opens holography up as an artistic technique. Recently rainbow holography has been very popular to display such objects.

The Fractional Order Fourier Transform and Fresnel Diffraction

Pierre Pellat-Finet, University of Southern Brittany, Lorient, France

Introduction

The fractional order Fourier transform is an extension of the standard Fourier transform. Let α be a complex number and let f be a function of two real variables. The 2-dimensional fractional Fourier transform of order α of f is defined by

$$\mathcal{F}_\alpha[f](\vec{\sigma}) = \frac{ie^{-i\alpha}}{\sin \alpha} \exp(-i\pi\sigma^2 \cot \alpha) \int_{\mathbb{R}^2} \exp(-i\pi\rho^2 \cot \alpha) \exp\left(\frac{2i\pi\vec{\sigma} \cdot \vec{\rho}}{\sin \alpha}\right) f(\vec{\rho}) d\vec{\rho} \quad (1)$$

where $\vec{\rho}$ and $\vec{\sigma}$ are 2-dimensional real vectors. The standard Fourier transform is $\mathcal{F}_{\pi/2}$, and $\mathcal{F}_0[f] = f$ for every function f . Fractional order Fourier transforms compose according to $\mathcal{F}_\beta \circ \mathcal{F}_\alpha = \mathcal{F}_{\beta+\alpha}$.

The integral expression of $\mathcal{F}_\alpha$ in Eq. (1) is similar to the integral expression of Fresnel diffraction, so that it is possible to express Fresnel diffraction phenomena in the form of fractional order Fourier transforms and to then develop a method for analyzing and solving some problems of diffraction and light propagation.

Diffraction-Propagation From a Spherical Emitter to a Spherical Receiver

If $\mathcal{A}$ is a spherical emitter or receiver (a spherical segment) with vertex Ω_A and curvature center C_A , its radius of curvature is $R_A = \overline{\Omega_A C_A}$ (Fig. 1). We choose Cartesian coordinates x, y on $\mathcal{A}$ with origin at Ω_A , and use the spatial vector $\vec{r} = (x, y)$ to localize a point on $\mathcal{A}$. We denote $r = \|\vec{r}\| = (x^2 + y^2)^{1/2}$ and $d\vec{r} = dx dy$. We consider monochromatic waves whose wavelength is λ in the propagation medium, which is assumed to be isotropic and homogeneous.

In the framework of a scalar theory of diffraction, the field transfer from a spherical emitter $\mathcal{A}$ (radius R_A , coordinates $\vec{r}$) to a spherical receiver $\mathcal{B}$ (radius R_B , coordinates $\vec{s}$) at a distance D (taken from vertex to vertex, Fig. 1) is expressed by

$$U_B(\vec{s}) = \frac{i}{\lambda D} \exp\left[-\frac{i\pi}{\lambda} \left(\frac{1}{R_B} + \frac{1}{D}\right) s^2\right] \int_{\mathbb{R}^2} \exp\left[-\frac{i\pi}{\lambda} \left(\frac{1}{D} - \frac{1}{R_A}\right) r^2\right] \exp\left(\frac{2i\pi}{\lambda D} \vec{r} \cdot \vec{s}\right) U_A(\vec{r}) d\vec{r} \quad (2)$$

where U_A is the complex (electric) field amplitude on $\mathcal{A}$, and U_B on $\mathcal{B}$. A constant multiplicative phase factor, of the form $\exp(-2i\pi D/\lambda)$, has been omitted in Eq. (2).

Eq. (2) generally corresponds to a Fresnel diffraction phenomenon. If $D = R_A$, we obtain a Fraunhofer phenomenon; moreover if $R_B = -R_A$, the field amplitude U_B is the spatial standard Fourier transform of U_A and the sphere $\mathcal{B}$ is called the Fourier sphere of $\mathcal{A}$, denoted by $\mathcal{F}$ (see Fig. 2).

Mathematical Expression of Diffraction Through a Fractional Order Fourier Transform

The similarity between Eqs. (1) and (2) should be clear. To express Eq. (2) by using a fractional order Fourier transform we proceed as follows. Let K be such that

$$K = \left(1 - \frac{D}{R_A}\right) \left(1 + \frac{D}{R_B}\right) \quad (3)$$

Fig. 1 Describing the field transfer by diffraction-propagation from the spherical emitter $\mathcal{A}$ to the spherical receiver $\mathcal{B}$ at a distance $D = \overline{\Omega_A \Omega_B}$. Generally we have a Fresnel diffraction phenomenon.

Fig. 2 If $D=R_A=-R_B$, light propagates from $\mathcal{A}$ to its Fourier sphere $\mathcal{F}$ according to a Fraunhofer diffraction phenomenon.

For the sake of simplicity we assume $0 \leq K \leq 1$, and we define α (a real number) by

$$\cos^2 \alpha = K, \quad -\pi \leq \alpha \leq \pi, \quad \alpha D \geq 0 \quad (4)$$

An equivalent definition, that is useful in some derivations, is

$$\cot^2 \alpha = \frac{(D+R_B)(R_A-D)}{D(D-R_A+R_B)}, \quad -\pi \leq \alpha \leq \pi, \quad \alpha D \geq 0 \quad (5)$$

We then define auxiliary parameters ε_A and ε_B by

$$\varepsilon_A = \frac{D}{R_A - D} \cot \alpha, \quad \varepsilon_A R_A > 0 \quad (6)$$

$$\varepsilon_B = \frac{D}{R_B + D} \cot \alpha \quad (7)$$

(Then, necessarily $\varepsilon_B R_B > 0$.)

Eventually we choose scaled spatial variables $\vec{\rho}$ on $\mathcal{A}$ and $\vec{\sigma}$ on $\mathcal{B}$ according to

$$\vec{\rho} = \frac{\vec{r}}{\sqrt{\lambda \varepsilon_A R_A}}, \quad \vec{\sigma} = \frac{\vec{s}}{\sqrt{\lambda \varepsilon_B R_B}} \quad (8)$$

We use scaled field amplitudes V_A on $\mathcal{A}$ and V_B on $\mathcal{B}$ such that

$$V_A(\vec{\rho}) = \sqrt{\frac{\varepsilon_A R_A}{\lambda}} U_A(\sqrt{\lambda \varepsilon_A R_A} \vec{\rho}), \quad V_B(\vec{\sigma}) = \sqrt{\frac{\varepsilon_B R_B}{\lambda}} U_B(\sqrt{\lambda \varepsilon_B R_B} \vec{\sigma}) \quad (9)$$

Then, Eq. (2) becomes

$$V_B(\vec{\sigma}) = e^{i\alpha} \mathcal{F}_\alpha[V_A](\vec{\sigma}) \quad (10)$$

Eq. (10) expresses a Fresnel diffraction phenomenon in the form of a fractional Fourier transform whose order depends on the propagation distance and the radii of the emitter and the receiver. Fraunhofer diffraction is obtained for $\alpha = \pi/2$.

If $K > 1$ or $K < 0$, the order α becomes a complex number and also corresponds to some diffraction phenomenon, depending on propagation distance and radii of curvature.

In order to not repeat definitions of parameters everytime, we will write

$$(R_A, R_B, D, \vec{r}, \vec{s}, U_A, U_B, \lambda) \leftrightarrow (\alpha, \varepsilon_A, \varepsilon_B, \vec{\rho}, \vec{\sigma}, V_A, V_B) \quad (11)$$

to indicate the correspondence between physical parameters and variables (on the left side) and fractional parameters, scaled variables and scaled field amplitudes (on the right side).

Representing diffraction through a fractional order Fourier transform is in accordance with two basic features of light propagation:

1. Continuity of light propagation. Fractional order Fourier transforms are such that $\mathcal{F}_\alpha[f] \rightarrow \mathcal{F}_\beta[f]$ if $\alpha \rightarrow \beta$, for every function f . Near the emitter, we have $\alpha=0$ and $\mathcal{F}[V_A] = V_A$; there is no diffraction. Near the Fourier sphere ($D=R_A$) we have a Fourier transform $\mathcal{F}_{\pi/2}$ and a Fraunhofer diffraction. Physically there is a continuous succession of diffraction phenomenae, from no diffraction (near the emitter) to a Fraunhofer diffraction (near the Fourier sphere), passing by intermediate Fresnel type phenomenae (see Fig. 3).
2. The composition law of fractional order Fourier transforms is in accordance with the Huygens-Fresnel principle that establishes that diffraction from $\mathcal{A}_1$ to $\mathcal{A}_2$ (represented by $\mathcal{F}_\alpha$) can be seen as the succession of two diffraction phenomenae : from $\mathcal{A}_1$ to $\mathcal{A}_3$ ($\mathcal{F}_{\alpha_1}$) and from $\mathcal{A}_3$ to $\mathcal{A}_2$ ($\mathcal{F}_{\alpha_2}$), where $\mathcal{A}_3$ is an intermediate spherical segment ; then $\mathcal{F}_\alpha = \mathcal{F}_{\alpha_2} \circ \mathcal{F}_{\alpha_1}$ and $\alpha = \alpha_1 + \alpha_2$ (see Fig. 4).

Fig. 3 Various values of α for various receivers: $0 < \alpha_1 < \alpha_2 < \pi/2 < \alpha_3$. The parameter α varies continuously when the receiver moves along the propagation axis.

Fig. 4 Illustrating the accordance between the composition law of fractional order Fourier transforms and the Huygens-Fresnel principle: $\alpha = \alpha_1 + \alpha_2$, so that $\mathcal{F}_\alpha = \mathcal{F}_{\alpha_2} \circ \mathcal{F}_{\alpha_1}$.

Fig. 5 The refracting surface, separating two propagation media with refractive indices n and n' .

Working With Fractional Orders

The basic idea is that problems in the scalar theory of diffraction can be solved by only manipulating fractional orders without explicitly writing corresponding integral expressions. We illustrate the method by considering imaging through a refracting spherical surface (vertex Ω_D , radius R_D , see Fig. 5). Let $\mathcal{A}$ be the object (spherical emitter), in the object space (with refractive index n), and let $\mathcal{A}'$ be a receiver in the image space (refractive index n'). We denote $d = \overline{\Omega_D \Omega_A}$ and $d' = \overline{\Omega_D \Omega_{A'}}$, as usual in geometrical optics (d is opposite to the distance of propagation from $\mathcal{A}$ to $\mathcal{D}$).

According to the Huygens-Fresnel principle, the field transfer from $\mathcal{A}$ to $\mathcal{A}'$ is the composition of two transfers: from $\mathcal{A}$ to $\mathcal{D}$ and from $\mathcal{D}$ to $\mathcal{A}'$. The corresponding mathematical expression could be obtained by the composition of two integrals that are like the one in Eq. (2). This is a cumbersome method that can be greatly simplified if we use the fractional Fourier transforms associated with light propagation.

The field transfer from $\mathcal{A}$ to $\mathcal{D}$ is described by

$$\left(R_A, R_D, -d, \vec{r}, \vec{s}, U_A, U_D, \lambda \right) \leftrightarrow \left(\alpha, \varepsilon_A, \varepsilon_D, \vec{\rho}, \vec{\sigma}, V_A, V_D \right) \quad (12)$$

and leads to

$$V_D = e^{i\alpha} \mathcal{F}_\alpha[V_A] \quad (13)$$

The field transfer from $\mathcal{D}$ to $\mathcal{A}'$ corresponds to

$$\left(R_D, R_{A'}, d', \vec{s}, \vec{r}', U_D, U_{A'}, \lambda'\right) \leftrightarrow \left(\alpha', \varepsilon'_D, \varepsilon'_A, \vec{\sigma}', \vec{\rho}', V'_D, V'_{A'}\right) \quad (14)$$

so that

$$V'_{A'} = e^{i\alpha'} \mathcal{F}_{\alpha'}[V'_D] \quad (15)$$

The composition of fractional transforms in Eqs. (13) and (15) is possible only if scaled variables on $\mathcal{D}$, $\vec{\sigma}$ and $\vec{\sigma}'$, are identical for both transfers, in order to obtain $V'_D = V_D$. This happens if $\lambda \varepsilon_D = \lambda' \varepsilon'_D$, that is, if

$$\frac{-\lambda d}{R_D - d} \cot \alpha = \frac{\lambda' d'}{R_D - d'} \cot \alpha' \quad (16)$$

For every function f we have $\mathcal{F}_0[f] = f$ and $\mathcal{F}_\pi[f](\vec{\sigma}) = f(-\vec{\sigma})$, so that the field amplitude on $\mathcal{A}'$ is the image of the field amplitude on $\mathcal{A}$ if $\alpha + \alpha' = 0$ or if $\alpha' + \alpha = \pi$ (inverted image). Then $\cot \alpha = -\cot \alpha'$, and since $n\lambda = n'\lambda'$, we deduce from Eq. (16)

$$\frac{n'}{d'} = \frac{n}{d} + \frac{n' - n}{R_D} \quad (17)$$

Eq. (17) is the relation of conjugation of the refracting surface. It has been deduced from a scalar theory of diffraction without writing any integral, but adequately managing parameters of the involved fractional order Fourier transforms.

The imaging between $\mathcal{A}$ and $\mathcal{A}'$ is expressed by $V'_{A'}(\vec{\sigma}') = V_A(\vec{\sigma}')$, if $\alpha + \alpha' = 0$, and by $V'_{A'}(\vec{\sigma}') = V_A(-\vec{\sigma}')$, if $\alpha + \alpha' = \pi$.

We now examine the curvature of the receiver. We denote $q = \Omega_A C_A = d + R_A$ and $q' = \Omega_{A'} C_{A'} = d' + R_{A'}$. Since $\cot \alpha = -\cot \alpha'$, we use Eq. (5) and write

$$\frac{(R_D - d)(R_A + d)}{d(d + R_A - R_D)} = \frac{(d' + R_{A'})(R_D - d')}{d'(d' - R_D + R_{A'})} \quad (18)$$

We use Eq. (16) with $\cot \alpha' = -\cot \alpha$, and deduce from Eq. (18) the relation

$$\frac{q}{n(q - R_D)} = \frac{q'}{n'(q' - R_D)} \quad (19)$$

that is

$$\frac{n'}{q'} = \frac{n}{q} + \frac{n' - n}{R_D} \quad (20)$$

Eq. (20) is the conjugaison relationship written for the curvature centers of $\mathcal{A}$ y $\mathcal{A}'$. We conclude that $\mathcal{A}'$ is the image of $\mathcal{A}$ if, and only if, the vertices of $\mathcal{A}$ and $\mathcal{A}'$ are conjugated and their centers are also conjugated.

Image Formation by a Lens

The use of fractional Fourier transforms in diffraction theory leads us to generalize one of the most important results in modern optics: the field amplitude of an image formed by a lens is the convolution of the object field amplitude with the Fourier transform of the pupil function of the lens. More precisely, we refer to Fig. 6 where a lens images the spherical emitter $\mathcal{A}$ (vertex Ω_A) on the spherical receiver $\mathcal{A}'$ (vertex $\Omega_{A'}$). If g_v denotes the transversal magnification at points Ω_A and $\Omega_{A'}$ we consider first the geometrical image field amplitude U_{GA} on $\mathcal{A}'$, defined by

$$U_{GA}(\vec{r}') = \frac{1}{g_v} U_A\left(\frac{\vec{r}'}{g_v}\right) \quad (21)$$

Fig. 6 Image formation by a lens, corresponding to Eq. (23).

We introduce the entrance pupil of the lens, say $\mathcal{P}$, located at Ω_p , and the exit pupil $\mathcal{P}'$ at $\Omega_{p'}$, which is the image of the entrance pupil through the lens. The pupil function of the lens is p such that $p(\vec{s}) = 1$, if the point $\vec{s}$ lays inside the pupil, and $p(\vec{s}) = 0$, if not. Let $d = \overline{\Omega_p \Omega_A}$ and let h be the function such that

$$h(\vec{r}) = \frac{1}{\lambda g_v^2 d^2} \mathcal{F}_{\pi/2}[p]\left(\frac{\vec{r}}{\lambda g_v d}\right) \quad (22)$$

Then the field amplitude on $\mathcal{A}'$ is given by

$$U_{A'} = h * U_{GA} \quad (23)$$

Although very important, Eq. (23) rigorously holds, indeed, only if $\mathcal{A}$ is centered on the entrance pupil $\mathcal{P}$, as shown in Fig. 6 (It can be shown that $\mathcal{A}'$ is centered on the exit pupil.). It does not hold for an arbitrary emitter, not centered on the pupil; nor if the object is the entrance pupil of the lens (whose image is the exit pupil).

By using the fractional Fourier transform representation of diffraction, the previous result can be extended to emitters that are not centered on the entrance pupil. For that purpose we first define the fractional convolution product of functions f and g by

$$f *_{\alpha} g = \mathcal{F}_{-\alpha}[\mathcal{F}_{\alpha}[f] \mathcal{F}_{\alpha}[g]] \quad (24)$$

We have $f *_{\alpha} g = fg$ and $f *_{\pi/2} g = f * g$, where $*$ denotes the standard convolution product.

Let α be the order of the fractional Fourier transform associated with the field transfer from $\mathcal{A}$ to $\mathcal{P}$. We introduce scaled variables and amplitudes V_A on $\mathcal{A}$ and $V_{A'}$ on $\mathcal{A}'$. If p_s is the scaled pupil function and $h_s = \mathcal{F}_{\alpha}[p_s]$ then

$$V_{A'} = h_s *_{\alpha} V_{GA} \quad (25)$$

Eq. (25) is a general expression for image formation by a lens, taking into account the effect of the lens aperture. It holds whatever the position of the object and of its curvature center. If $\mathcal{P}$ is located on the Fourier sphere of $\mathcal{A}$, since $\alpha = \pi/2$, we obtain Eq. (23) once more. If $\mathcal{A}$ is located on the pupil, we obtain $\alpha = 0$ and the result is compatible with the fact that the field on the exit pupil is identical to the field on the entrance pupil (since pupils are conjugated).

Optical Resonator Stability

An optical resonator is made up of two spherical mirrors, say $\mathcal{M}_1$ (radius R_1) and $\mathcal{M}_2$ (radius R_2). Expressing propagation from a mirror to the other by using a fractional order Fourier transform leads us to a complete theory of optical resonators, based on a scalar diffraction theory. Once more, the main interest of the method is deduce results without explicitly writing integrals, but suitably manipulating fractional orders of involved fractional Fourier transforms.

The field transfer from a mirror to the other can be expressed by a fractional Fourier transform whose order α depends on the distance between the mirrors and their radii. This holds true for the reverse transfer, so that a round trip is expressed by the composition of two fractional order Fourier transforms. It can be shown that the orders are the same for both transfers, so that a round trip from $\mathcal{M}_1$ to $\mathcal{M}_1$ is expressed in the form

$$V_1 = e^{-4i\pi D/\lambda} e^{2i\alpha} \mathcal{F}_{2\alpha}[V_1] \quad (26)$$

where V_1 is the scaled field amplitude on $\mathcal{M}_1$ and where the phase factor that was omitted in Eq. (2) has been reintroduced.

A distinction should be made according to whether α is a real or a complex number. If α is real, there is a phase shift in the round trip, and the resonator is said to be stable. If α is a complex number, there is an attenuation of the field amplitude, which is due to diffraction losses; the resonator is said to be unstable.

We state: an optical resonator is stable if, and only if, the field transfer from a mirror to the other is expressed by a fractional Fourier transform whose order is a real number. According to Eqs. (3) and (4) we conclude that an optical resonator is stable if, and only if,

$$0 \leq \left(1 - \frac{D}{R_1}\right) \left(1 - \frac{D}{R_2}\right) \leq 1 \quad (27)$$

(The sign of R_2 in Eq. (27) is opposite to the sign of R_B in Eq. (3), because light propagation direction is changed after reflexion on the corresponding mirror).

Eq. (27) is a very well known condition for a resonator to be stable.

Another consequence of Eq. (26) is that field amplitudes of waves that propagate inside the resonator are eigenfunctions of fractional Fourier transforms (whatever the order). These eigenfunctions are Hermite-Gauss functions, of the form

$$\varphi_{m,n}(\xi, \eta) = H_m(\sqrt{2\pi}\xi) H_n(\sqrt{2\pi}\eta) \exp[-\pi(\xi^2 + \eta^2)] \quad (28)$$

where H_m is the Hermite polynomial of integer order m . Hence the notion of Hermite-Gauss modes of an optical resonator.

Eq. (26) also leads to find longitudinal modes of a resonator. For every integer m , we have

$$\mathcal{F}_{\alpha}[H_m] = e^{2im\alpha} H_m \quad (29)$$

so that for $V_1 = \varphi_{m,n}$ we deduce from Eq. (26)

$$\varphi_{m,n} = e^{-4i\pi D/\lambda} e^{2i\alpha} e^{2i(m+n)\alpha} \varphi_{m,n} \quad (30)$$

and necessarily

$$\frac{2\pi D}{\lambda} - (1 + m + n)\alpha = k\pi \quad (31)$$

where k is an integer. Only waves whose wavelengths satisfy Eq. (31) can propagate in the resonator. They are the longitudinal modes of the resonator.

Gaussian Beams and Gouy Phase

A laser with a stable optical cavity (or resonator) generates Gaussian beams, which are modes of the laser resonator and are described by Hermite-Gauss functions. It can be shown that a Gaussian beam admits a minimal area, called the beam waist and located on a plane (while other wave surfaces are spherical segments). At a distance d from the waist, the Gaussian beam wave surface is a sphere whose curvature radius is R and the field propagation from the beam waist to the previously described surface is expressed by a fractional Fourier transform whose order is α_d with

$$\tan \alpha_d = \frac{\lambda d}{\pi w_0^2} \quad (32)$$

If the phase origine is taken on the waist plane, the field amplitude at a distance d is

$$U_{m,n}(x, y, d) = U_0 \frac{w_0}{w_d} H_m\left(\frac{\sqrt{2}}{w_d} x\right) H_n\left(\frac{\sqrt{2}}{w_d} y\right) \exp\left[-\frac{x^2 + y^2}{w_d^2} - \frac{2i\pi d}{\lambda} + i(m + n + 1)\alpha_d\right] \quad (33)$$

and $(m + n + 1)\alpha_d$ is no more than the Gouy phase.

Uncoupling Variables

A 2-dimensional fractional Fourier transform can be seen like the composition of two 1-dimensional transforms, a fact that can be adequately applied in optics.

We denote by $\mathcal{F}_\alpha^{[1]}$ the 1-dimensional Fourier transform of order α (a real number), defined by

$$\mathcal{F}_\alpha^{[1]}[f](\eta) = \frac{\exp\left[i\left(\frac{\pi}{4}s(\alpha) - \frac{\alpha}{2}\right)\right]}{\sqrt{|\sin \alpha|}} \exp(-i\pi\eta^2 \cot \alpha) \int_{\mathbb{R}} \exp(-i\pi\xi^2 \cot \alpha) \exp\left(\frac{2i\pi\xi\eta}{\sin \alpha}\right) f(\xi) d\xi \quad (34)$$

where $s(\alpha)$ denotes the sign of α .

The Fubini theorem leads us to compose two 1-dimensional fractional order Fourier transforms according to the following diagram, where $\mathcal{F}_{\alpha_1}^{[1]}$ operates on the variable ξ_1 , and $\mathcal{F}_{\alpha_2}^{[1]}$ on ξ_2 ,

$$\begin{array}{ccc} f(\xi_1, \xi_2) & \xrightarrow{\mathcal{F}_{\alpha_1}^{[1]}} & \mathcal{F}_{\alpha_1}^{[1]}[f](\eta_1, \xi_2) \\ \downarrow \mathcal{F}_{\alpha_2}^{[1]} & & \downarrow \mathcal{F}_{\alpha_2}^{[1]} \\ \mathcal{F}_{\alpha_2}^{[1]}[f](\xi_1, \eta_2) & \xrightarrow{\mathcal{F}_{\alpha_1}^{[1]}} & \mathcal{F}_{\alpha_1, \alpha_2}[f](\eta_1, \eta_2) \end{array} \quad (35)$$

where $\mathcal{F}_{\alpha_1, \alpha_2}$ is a 2-dimensional integral. We remark that $\mathcal{F}_{\alpha, \alpha}$ is no more than the 2-dimensional fractional order Fourier transform defined in Eq. (1).

The previous decomposition is useful when dealing with optical emitters and receivers that are segments of tori, that is, have two radii of curvature (see Fig. 7). We consider a toric emitter $\mathcal{A}$ (coordinates x_1 and x_2 , taken along principal sections) and a toric receiver $\mathcal{B}$ (coordinates x'_1 and x'_2) respectively at a distance D . We assume that principal sections of $\mathcal{A}$ and $\mathcal{B}$ are along parallel axes: $x'_1 \parallel x_1$ and $x'_2 \parallel x_2$ (see Fig. 7). Let R_1 and R_2 be the principal radii of $\mathcal{A}$ and R'_1 and R'_2 those of $\mathcal{B}$.

We consider a first 1-dimensional fractional Fourier transform for the transfer from $\mathcal{A}$ to $\mathcal{B}$ but only for the x_1 and x'_1 variables. We define α_1 by

$$\cos^2 \alpha_1 = \left(1 - \frac{D}{R_1}\right) \left(1 + \frac{D}{R'_1}\right) \quad (36)$$

and then

$$\varepsilon_1 = \frac{D}{R_1 - D} \cot \alpha_1, \quad \varepsilon'_1 = \frac{D}{R'_1 + D} \cot \alpha_1 \quad (37)$$

Fig. 7 Describing the field transfer by diffraction-propagation from a toric emitter A to a toric receiver B .

Scaled variables are

$$\xi_1 = \frac{x_1}{\sqrt{\lambda \varepsilon_1 R_1}}, \quad \xi'_1 = \frac{x'_1}{\sqrt{\lambda \varepsilon'_1 R'_1}} \quad (38)$$

and scaled functions

$$V_1(\xi_1, x_2) = \sqrt[4]{\frac{\varepsilon_1 R_1}{\lambda}} U_A\left(\sqrt{\lambda \varepsilon_1 R_1} \xi_1, x_2\right), \quad V'_1(\xi'_1, x_2) = \sqrt[4]{\frac{\varepsilon'_1 R'_1}{\lambda}} U_B\left(\sqrt{\lambda \varepsilon_1 R_1} \xi'_1, x'_2\right) \quad (39)$$

We then obtain

$$V'_1(\xi'_1, x_2) = e^{i x_1/2} \mathcal{F}_{\alpha_1}^{[1]}[V_1](\xi'_1, x_2) \quad (40)$$

Then, we consider a second 1-dimensional Fourier transform for the transfer from A to B but for the x_2 and x'_2 variables. We define $\alpha_2, \varepsilon_2, \varepsilon'_2, \xi_2$ and ξ'_2 as $\alpha_1, \varepsilon_1, \varepsilon'_1, \xi_1$ and ξ'_1 , after changing R_1 into R_2 and R'_1 into R'_2 in Eqs. (36)–(38). Scaled field amplitudes on A and B are

$$V_A(\xi_1, \xi_2) = \sqrt[4]{\frac{\varepsilon_2 R_2}{\lambda}} V_1\left(\xi_1, \sqrt{\lambda \varepsilon_2 R_2} \xi_2\right) \quad (41)$$

$$V_B(\xi'_1, \xi'_2) = \sqrt[4]{\frac{\varepsilon'_2 R'_2}{\lambda}} V'_1\left(\xi'_1, \sqrt{\lambda \varepsilon_2 R_2} \xi'_2\right) \quad (42)$$

so that

$$V_B(\xi'_1, \xi'_2) = e^{i x_2/2} \mathcal{F}_{\alpha_2}^{[1]}[V'_1](\xi'_1, \xi'_2) = e^{i(x_1+x_2)/2} \mathcal{F}_{\alpha_2}^{[1]}\left[\mathcal{F}_{\alpha_1}^{[1]}[V_1]\right](\xi'_1, \xi'_2) = e^{i(x_1+x_2)/2} \mathcal{F}_{\alpha_1, \alpha_2}[V_A](\xi'_1, \xi'_2) \quad (43)$$

Eq. (43) is a generalization of Eq. (10).

The method can be applied to deal with toric (or astigmatic) refractive surfaces and astigmatic lenses. It also provides a method for analyzing propagation and imaging of Gaussian beams with elliptical waists, like those produced by some laser diodes.

Ambiguity Function in Optics

JP Guigay, European Synchrotron Radiation Facility (ESRF), Grenoble, France

Introduction

The ambiguity function (AF) associated to a time signal $s(t)$ is defined as the following two-dimensional time-frequency function

$$A(\tau, f) = \int dt s^*(t) s(t - \tau) \exp(-i2\pi ft) \quad (1)$$

It has been introduced by Woodward (1953) in the theory of signal processing of radar or sonar measurements, τ being the delay time related to the distance of the target and f the frequency shift due to its velocity. It bears in its name the idea that it is impossible to perform arbitrarily accurate measurements of both the distance and the velocity of the target. The well-known reason is that the width of a signal in the time domain is inversely proportional to its width in the frequency domain (a narrower signal has a wider spectrum and inversely). From the mathematical point of view, this is just a property of the Fourier transformation; from the physical point of view, this is a common property for waves of any kind and is the basis of the well-known uncertainty relations in quantum physics.

It was shown by Papoulis (1974) that the AF concept can be used in Fourier optics, considering the propagation of a spatially coherent quasi-monochromatic optical field $\psi_z(x)$ transmitted through slit apertures and thin lenses, in the conditions of paraxial propagation in the z -direction; the considered AF is then defined as the following Fourier transform with respect to x :

$$A_z(a, f) = \int dx \psi_z^*(x - a/2) \psi_z(x + a/2) \exp(-i2\pi fx) \quad (2)$$

In the present paper, it will be shown that the concept of AF in optics can be considered as an extension of the spectral analysis of images; the images are two-dimensional intensity patterns $I(x, y)$ which can often be analyzed in a convenient way by considering their Fourier transform (intensity spectrum):

$$\tilde{I}(u, v) = \iint dx dy I(x, y) \exp[-i2\pi(ux + vy)] \quad \text{or} \quad \tilde{I}(\vec{f}) = \int d\vec{x} I(\vec{x}) \exp[-i2\pi\vec{x} \cdot \vec{f}] \quad (3)$$

where two-dimensional vectors are used; the variables (u, v) are the spatial frequencies conjugate to the coordinates (x, y) .

Definition in Terms of the Mutual Intensity

Besides the intensity distribution, the phase correlation between an arbitrary pair of points must be included for a complete description of the optical field. For this purpose, it seems natural to generalize $I(\vec{x})$ by the mutual intensity $\rho(\vec{x}, \vec{x}') = \sqrt{I(\vec{x})I(\vec{x}')} \gamma(\vec{x}, \vec{x}')$, where $\gamma(\vec{x}, \vec{x}')$ is the complex degree of coherence associated to the pair of points $(\vec{x}, \vec{x}')$ (see Born and Wolf (1999)). The mutual intensity is reduced to the usual intensity $I(\vec{x})$ when these two points coincide. The ambiguity is defined (Guigay, 1978), in the frame of Phase-Space Optics (PSO), as the Fourier transform with respect to $\vec{x}$ of the mutual-intensity written as $\rho(\vec{x} + \vec{a}/2, \vec{x} - \vec{a}/2)$:

$$A(\vec{f}, \vec{a}) = \int d\vec{x} \exp(-i2\pi\vec{x} \cdot \vec{f}) \rho(\vec{x} + \vec{a}/2, \vec{x} - \vec{a}/2) \quad (4)$$

$A(\vec{f}, \vec{a})$ is defined in the phase-space which is a four-dimensional space, since $\vec{f}$ and $\vec{a}$ are two-dimensional vectors. It represents a complete description of the partially coherent field optical field. The equivalent representation

$$A(\vec{f}, \vec{a}) = \int d\vec{m} \exp(i2\pi\vec{m} \cdot \vec{a}) \tilde{\rho}(\vec{m} + \vec{f}/2, \vec{m} - \vec{f}/2) \quad (5)$$

is obtained by replacing the mutual-intensity by its Fourier expansion with respect to $\vec{x}$

$$\rho(\vec{x} + \vec{a}/2, \vec{x} - \vec{a}/2) = \iint d\vec{g} d\vec{h} \exp\{i2\pi[\vec{g} \cdot (\vec{x} + \vec{a}/2) - \vec{h} \cdot (\vec{x} - \vec{a}/2)]\} \tilde{\rho}(\vec{g}, \vec{h}) \quad (6)$$

Formula (4) shows that $A(\vec{f}, 0)$ represents the intensity spectrum defined in (3), which, as well as $I(\vec{x})$, represents the experimental data recorded by a digital detector. Formula (5) shows that $A(0, \vec{a})$ is the inverse Fourier transform of the intensity distribution $\tilde{\rho}(\vec{m}, \vec{m})$ in Fourier space.

A particularly important phase-space function is the Wigner Distribution Function (WDF) which was introduced in optics by Bastiaans (1978) (see Testorf *et al.* (2010) for a precise account of its properties). The WDF is defined as the Fourier transform of $\rho(\vec{x} + \vec{a}/2, \vec{x} - \vec{a}/2)$ with respect to $\vec{a}$, instead of $\vec{x}$:

$$W(\vec{x}, \vec{g}) = \int d\vec{a} \exp(-i2\pi\vec{a} \cdot \vec{g}) \rho(\vec{x} + \vec{a}/2, \vec{x} - \vec{a}/2) \quad (7)$$

It can also be expressed as

$$W(\vec{x}, \vec{g}) = \int d\vec{m} \exp(i2\pi\vec{m} \cdot \vec{x}) \tilde{\rho}(\vec{g} + \vec{m}/2, \vec{g} - \vec{m}/2) \quad (8)$$

The mutual intensity can be obtained from the AF or from the WDF as

$$\rho\left(\vec{x} + \frac{\vec{a}}{2}, \vec{x} - \frac{\vec{a}}{2}\right) = \int d\vec{f} \exp(i2\pi\vec{f} \cdot \vec{x}) A(\vec{f}, \vec{a}) = \int d\vec{g} \exp(i2\pi\vec{g} \cdot \vec{a}) W(\vec{x}, \vec{g}) \quad (9)$$

The AF and the WDF are related to each-other by double Fourier transformation over the position and frequency variables:

$$A(\vec{f}, \vec{a}) = \int d\vec{x} \int d\vec{g} \exp[i2\pi(\vec{a} \cdot \vec{g} - \vec{f} \cdot \vec{x})] W(\vec{x}, \vec{g}) \quad (10)$$

$$W(\vec{x}, \vec{g}) = \int d\vec{a} \int d\vec{f} \exp[i2\pi(\vec{f} \cdot \vec{x} - \vec{a} \cdot \vec{g})] A(\vec{f}, \vec{a}) \quad (11)$$

The property $\rho(\vec{x}, \vec{x}) = (\rho(\vec{x}, \vec{x}))^*$ of the mutual intensity shows that the AF, in general complex, satisfies the relation $A(-\vec{f}, -\vec{a}) = [A(\vec{f}, \vec{a})]^*$. It also shows that the WDF is real (but can be negative as well as positive).

In the exit plane of an object of transmittance $T(\vec{x})$, under uniform coherent illumination, the mutual intensity is equal to the product $T(\vec{x} + \vec{a}/2)T^*(\vec{x} - \vec{a}/2)$ which is often referred to as the “product-space-representation” of the signal $T(\vec{x})$; The corresponding AF and WDF, which are referred to as the AF and the WDF associated to $T(\vec{x})$, are redundant representations of $T(\vec{x})$.

PSO representations are useful tools to characterize the performances of optical systems. They provide elegant approaches to the description and processing of optical signals or images. It has been shown by Nugent (2007) that the concept of AF can be used to unify the various noninterferometric approaches to phase retrieval.

In order to simplify the formulation of the following sections, we shall often consider one-dimensional fields, in which case the two-dimensional vectors are replaced by scalars, without a real lost of generality, because the extension to the general case is usually straightforward.

Intensity Spectrum of a Fresnel Diffraction Pattern Under Coherent Illumination

General Formulation

For simplicity, let us consider a plane wave, of wavelength λ , incident along the z -direction on a thin object of transmittance $T(\vec{x})$ in the plane $z=0$. In the conditions of Fresnel diffraction, the wave-function in a plane $z=D$ is

$$\psi_D(\vec{x}) = |\lambda D|^{-1/2} \exp\left(-i\frac{\pi}{4}\right) \int d\vec{\eta} \exp\left[i\pi \frac{(\vec{\eta} - \vec{x})^2}{\lambda D}\right] T(\vec{\eta}) \quad (12)$$

The corresponding intensity spectrum can be expressed by the multiple integral

$$\tilde{I}_D(\vec{f}) = \int d\vec{x} \exp(-i2\pi\vec{x} \cdot \vec{f}) \iint \frac{d\vec{\eta} d\vec{\eta}'}{\lambda D} \exp\left[i\pi \frac{(\vec{\eta} - \vec{x})^2 - (\vec{\eta}' - \vec{x})^2}{\lambda D}\right] T(\vec{\eta}) T^*(\vec{\eta}')$$

The integration over $\vec{x}$ results in the appearance of a two-dimensional delta-function

$$\int d\vec{x} \exp\left[-i2\pi\vec{x} \cdot \left(\vec{f} + \frac{\vec{\eta} - \vec{\eta}'}{\lambda D}\right)\right] = \lambda D \delta\left(\lambda D \vec{f} + \vec{\eta} - \vec{\eta}'\right) \quad (13)$$

and the intensity spectrum can therefore be reduced to a single integration (Guigay, 1977a,b):

$$\tilde{I}_D(\vec{f}) = \exp(-i\pi\lambda D \vec{f}^2) \int d\vec{\eta} \exp(-i2\pi\vec{f} \cdot \vec{\eta}) T(\vec{\eta}) T^*(\vec{\eta} + \lambda D \vec{f}) \quad (14)$$

This last formula can be expressed in symmetrical form:

$$\tilde{I}_D(\vec{f}) = \int d\vec{x} \exp(-i2\pi\vec{f} \cdot \vec{x}) T\left(\vec{x} - \frac{\lambda D \vec{f}}{2}\right) T^*\left(\vec{x} + \frac{\lambda D \vec{f}}{2}\right) \quad (15)$$

Similar expressions also exist in terms of $\tilde{T}(\vec{f})$:

$$\begin{aligned} \tilde{I}_D(\vec{f}) &= \exp(-i\pi\lambda D \vec{f}^2) \int d\vec{h} \exp(-i2\pi\lambda D \vec{h} \cdot \vec{f}) \tilde{T}(\vec{h} + \vec{f}) \tilde{T}^*(\vec{h}) \\ &= \int d\vec{h} \exp(-i2\pi\lambda D \vec{h} \cdot \vec{f}) \tilde{T}(\vec{h} + \vec{f}/2) \tilde{T}^*(\vec{h} - \vec{f}/2) \end{aligned} \quad (16)$$

It is interesting to note that the AF associated with $T(x)$ is apparent in this formulation if the intensity spectrum is formally considered as a function of f and $a = \lambda Df$.

Derivation of the Transport of Intensity Equation

By linearization of $T\left(\vec{x} - \frac{\lambda D\vec{f}}{2}\right)T^*\left(\vec{x} + \frac{\lambda D\vec{f}}{2}\right)$ as $T(\vec{x})T^*(\vec{x}) + \lambda D\vec{f} \cdot [T\vec{\partial}T^* - T^*\vec{\partial}T]$, where $\vec{\partial}T$ denotes the two-dimensional gradient of the function $T(\vec{x}) = \sqrt{I_0(\vec{x})}\exp[i\phi(\vec{x})]$ written in terms of its modulus and its phase, we obtain the following approximation of formula (15) in the case of small values of $|\lambda D\vec{f}|$:

$$\tilde{I}_D(\vec{f}) = \tilde{I}_0(\vec{f}) - i\lambda D\vec{f} \cdot \int d\vec{x} \exp(-i2\pi\vec{f} \cdot \vec{x}) I_0(\vec{x}) \vec{\partial}(\vec{x})$$

By inverse Fourier transformation of this last formula, we obtain the well-known transport of intensity equation (Teague, 1983):

$$I_D(\vec{x}) = I_0(\vec{x}) - \frac{\lambda D}{2\pi} \vec{\partial} \cdot [I_0(\vec{x}) \vec{\partial}(\vec{x})] \quad (17)$$

which is widely used for phase retrieval.

Application to Simple Objects

This formulation can provide interesting results for some typical Fresnel diffraction patterns; for instance, in the one-dimensional case of a slit of full-width w , we obtain (Guigay, 1977b):

$$\tilde{I}_D(f) = \int_{-(w-|\lambda Df|)/2}^{(w-|\lambda Df|)/2} dx e^{-i2\pi fx} = \frac{\sin[\pi f(w-|\lambda Df|)]}{\pi f} \text{ for } |f| \leq \frac{w}{\lambda D}, \quad 0 \text{ otherwise} \quad (18)$$

Note that this expression is analytically much simpler than the intensity distribution $I(x)$ expressed in terms of Fresnel integrals represented geometrically by the Cornu spiral (see Born and Wolf (1999)).

Contrast Transfer Functions

Considering $T(\vec{x}) = \exp[-B(\vec{x}) + i\phi(\vec{x})]$, where $\exp[-B(\vec{x})]$ and $\phi(\vec{x})$ are the absorption and the phase modulations of the object, we can introduce in formula (11) the approximation

$$T^*\left(\vec{x} + \frac{\lambda D\vec{f}}{2}\right)T\left(\vec{x} - \frac{\lambda D\vec{f}}{2}\right) = 1 - B\left(\vec{x} + \frac{\lambda D\vec{f}}{2}\right) - B\left(\vec{x} - \frac{\lambda D\vec{f}}{2}\right) + i\left[\left(\vec{x} + \frac{\lambda D\vec{f}}{2}\right) - \left(\vec{x} - \frac{\lambda D\vec{f}}{2}\right)\right] \quad (19)$$

which should be valid under the conditions $0B(\vec{x})1$ (weak absorption) and $|\phi(\vec{x}) - \phi(\vec{x} - \lambda D\vec{f})|1$. This last condition is the slowly-varying phase condition (Testorf et al., 2010) which is less restrictive than the weak-phase condition $|\phi(\vec{x})|1$. Under such conditions, the intensity spectrum takes a simple linear form (Guigay, 1977a)

$$\tilde{I}_D(\vec{f}) = \delta(\vec{f}) - 2\cos\left(\pi\lambda D\vec{f}^2\right)\tilde{B}(\vec{f}) + 2\sin\left(\pi\lambda D\vec{f}^2\right)\tilde{\phi}(\vec{f}) \quad (20)$$

The factors of $\tilde{B}(\vec{f})$ and $\tilde{\phi}(\vec{f})$ are named as the absorption-transfer function (ATF) and the phase-transfer function (PTF) respectively.

Formula (20) can be generalized to the case of an imaging system with aberrations others than defocusing. In electron microscopy, for which primary spherical aberration characterized by the coefficient C_s is unavoidable, the following formula is to be used (Hanszen, 1972; Wade, 1974):

$$\tilde{I}_D(\vec{f}) = \delta(\vec{f}) - 2\cos[\omega(\vec{f})]\tilde{B}(\vec{f}) + 2\sin[\omega(\vec{f})]\tilde{\phi}(\vec{f}) \quad (21)$$

$$\text{with } \omega(\vec{f}) = \pi\left(\lambda D\vec{f}^2 + C_s\lambda^3\vec{f}^4/2\right) \quad (22)$$

Partial Talbot Effect

According to the Talbot effect, in the case of a periodic object of period a , a Fresnel diffraction amplitude identical to the object amplitude $T(x)$ is obtained at the so-called Talbot distance $D_T = a^2/\lambda$. It was shown in Guigay (1971) and Arrizón and Ojeda-Castañeda (1992) that the amplitude distribution at any intermediate distance equal to a rational fraction $(n'/n)D_T$ of the Talbot distance is a linear combination of n laterally shifted copies of $T(x)$; this is called the Fractional Talbot effect.

The intensity of any Fresnel diffraction pattern is itself a periodic function of $\vec{x}$ (the letter), also with periodicity a ; according to (15), its Fourier coefficient of order m (m integer) is

$$\tilde{I}_D\left(\frac{m}{a}\right) = \frac{1}{a} \int_{-a/2}^{a/2} dx \exp(-i2\pi x \frac{m}{a}) T^*\left(x + \frac{\lambda Dm}{2a}\right) T\left(x - \frac{\lambda Dm}{2a}\right) \quad (23)$$

This last formula shows that $\tilde{I}_D(pm/a) = \tilde{I}_0(m/a)$, with p being an integer, if the distance D is equal to D_T/m . This result may be named as the “the partial Talbot effect,” because it represents the conservation of a part of the intensity spectrum of the periodic object.

Propagation Through a Paraxial Optical System in Terms of AF

Propagation in Free Space

Let us consider the propagation in free space, with mean direction along the z -axis, of a partially coherent beam. The mutual intensity in the $z=D$ plane is given in terms of the mutual intensity in the $z=0$ plane as:

$$\begin{aligned} \rho_D\left(\vec{x} + \frac{\vec{a}}{2}, \vec{x} - \frac{\vec{a}}{2}\right) &= \frac{1}{\lambda D} \int d\vec{\eta} \exp\left[i\pi \frac{(\vec{\eta} - \vec{x})^2}{\lambda D}\right] \int d\vec{\xi} \exp\left[-i\pi \frac{(\vec{\xi} - \vec{x})^2}{\lambda D}\right] \rho_0\left(\vec{\eta} + \frac{\vec{a}}{2}, \vec{\xi} - \frac{\vec{a}}{2}\right) \\ &= \frac{1}{\lambda D} \int d\vec{\eta} \int d\vec{\xi} \exp\left[i\pi \frac{\eta^2 - \xi^2}{\lambda D} - 2i\pi \vec{x} \cdot \frac{\vec{\eta} - \vec{\xi}}{\lambda D}\right] \rho_0\left(\vec{\eta} + \frac{\vec{a}}{2}, \vec{\xi} - \frac{\vec{a}}{2}\right) \end{aligned}$$

After insertion of this expression in (4), it can be seen that the integration over x results in the delta-function $\lambda D \delta(\vec{\eta} - \vec{\xi} + \lambda D \vec{f})$. The multiple integral is thus reduced to a single integral.

$$\begin{aligned} A_D(\vec{f}, \vec{a}) &= \int d\vec{\eta} \exp(-i2\pi \vec{f} \cdot \vec{\eta}) \rho_0\left(\vec{\eta} + \frac{\vec{a} - \lambda D \vec{f}}{2}, \vec{\eta} - \frac{\vec{a} - \lambda D \vec{f}}{2}\right) \\ \text{Therefore } A_D(\vec{f}, \vec{a}) &= A_0(\vec{f}, \vec{a} - \lambda D \vec{f}) \end{aligned} \quad (24)$$

This represents a translation of amplitude $\lambda D \vec{f}$ of $A_0(\vec{f}, \vec{a})$ on the second variable.

This result can be more readily obtained by recalling that the Fresnel diffraction integral is the convolution of the input function $T(\vec{x})$ by the propagator $G(\vec{x}) = \exp(i\pi \vec{x}^2 / \lambda D - i\pi/4) / \sqrt{\lambda D}$; the output spectrum is therefore the product of the input spectrum $\tilde{T}(f)$ by the spectrum of $G(x)$ which is $\tilde{G}(f) = \exp(-i\pi \lambda D f^2)$; this is translated in terms of mutual intensity as

$$\begin{aligned} \tilde{\rho}_D(\vec{m} + \vec{f}/2, \vec{m} - \vec{f}/2) &= \exp\left\{-i\pi \lambda D \left[(\vec{m} + \vec{f}/2)^2 - (\vec{m} - \vec{f}/2)^2\right]\right\} \tilde{\rho}_0(\vec{m} + \vec{f}/2, \vec{m} - \vec{f}/2) \\ &= \exp(-i2\pi \lambda D \vec{m} \cdot \vec{f}) \tilde{\rho}_0(\vec{m} + \vec{f}/2, \vec{m} - \vec{f}/2) \end{aligned} \quad (25)$$

Inserting this expression in (5), we indeed obtain directly:

$$A_D(\vec{f}, \vec{a}) = \int d\vec{m} \exp[i2\pi \vec{m} \cdot (\vec{a} - \lambda D \vec{f})] \tilde{\rho}_0\left(\vec{m} + \frac{\vec{f}}{2}, \vec{m} - \frac{\vec{f}}{2}\right) = A_0(\vec{f}, \vec{a} - \lambda D \vec{f})$$

As shown in Bastiaans (1978), a similar formula also exists for the WDF:

$$W_D(\vec{x}, \vec{g}) = W_0(\vec{x} - \lambda D \vec{g}, \vec{g}) \quad (26)$$

According to formulas (24) and (26), the AF and the WDF propagate in a uniform medium without a change of their functional forms; only the variables are linearly transformed. This is an elegant representation of Fresnel diffraction phenomena.

Transmission Through a Thin Object

In this case, the incident mutual-intensity $\rho_{inc}(\vec{x}, \vec{x}')$ is multiplied by $T(\vec{x})T^*(\vec{x}')$, where $T(\vec{x})$ is the object transmittance; The AF of the incident beam is then to be convoluted with the object-AF $A_T(\vec{f}, \vec{a})$, as follows

$$A(\vec{f}, \vec{a}) = \int d\vec{h} A_{inc}(\vec{h}, \vec{a}) A_T(\vec{f} - \vec{h}, \vec{a}) \quad (27)$$

where $A_T(\vec{f}, \vec{a}) = \int d\vec{x} \exp(-i2\pi \vec{x} \cdot \vec{f}) T(\vec{x} + \vec{a}/2) T^*(\vec{x} - \vec{a}/2)$. The transmission by a thin lens of focal length F is of special interest; this lens behaves as an object of transmittance $\exp(-i\pi x^2 / \lambda F)$. With $\rho_{inc}(\vec{x} + \vec{a}/2, \vec{x} - \vec{a}/2)$ being the mutual intensity in the lens entrance surface, the AF in the lens exit surface is calculated as

$$\begin{aligned} A_{exit}(\vec{f}, \vec{a}) &= \int d\vec{x} \exp\left[-i2\pi \vec{x} \cdot \vec{f} - i\pi \frac{(\vec{x} + \vec{a}/2)^2 - (\vec{x} - \vec{a}/2)^2}{\lambda F}\right] \rho_{inc}(\vec{x} + \vec{a}/2, \vec{x} - \vec{a}/2) \\ &= \int d\vec{x} \exp\left[-i2\pi \vec{x} \cdot \left(\vec{f} + \frac{\vec{a}}{\lambda F}\right)\right] \rho_{inc}(\vec{x} + \vec{a}/2, \vec{x} - \vec{a}/2) \\ \text{Therefore } A_{exit}(\vec{f}, \vec{a}) &= A_{inc}\left(\vec{f} + \vec{a}/\lambda F, \vec{a}\right) \end{aligned} \quad (28)$$

This represents a translation of amplitude $(-\vec{a}/\lambda F)$ of $A_0(\vec{f}, \vec{a})$ on the first variable.

The corresponding formula for the WDF is easily found as:

$$W(\vec{x}, \vec{g}) = W_{inc}(\vec{x}, \vec{g} + \vec{x}/\lambda F) \quad (29)$$

Propagation in a Paraxial Optical System

Consider the following process: propagation from an input plane to a thin lens over a distance D_1 , then transmission by this lens of focal length F and finally propagation to the output plane over a distance D_2 . Performing the corresponding transformations successively, according to (24, 28), it is easy to obtain the output AF in terms of the input AF as:

$$A_{out}(\vec{f}, \vec{a}) = A_{in}(\vec{f} - \vec{f}D_2/F + \vec{a}/\lambda F, \vec{a} - \vec{a}D_1/F - \vec{f}\lambda(D_1 + D_2 - D_1D_2/F)) \quad (30)$$

This represents a translation of amplitude $\vec{f}D_2/F - \vec{a}/\lambda F$ on the first variable and a translation of amplitude $\vec{a}D_1/F + \vec{f}\lambda(D_1 + D_2 - D_1D_2/F)$ on the second variable.

This phase-space method is thus a convenient and elegant tool to describe the propagation of a coherent or partially coherent beam in any system comprising coaxial lenses and it is possible to use the WDF instead of the AF. The phase-space method is much simpler than the method based on the propagation of mutual-intensity which would involve convolutions integrals or Fourier transformations.

The AF in Space-Invariant (Isoplanatic) Imaging

The mutual intensity $\rho_{im}(\vec{x}, \vec{x}')$ in the image plane is given in terms of the mutual intensity $\rho_{ob}(\vec{x}, \vec{x}')$ in the object plane (for convenience, the magnification is set equal to 1) as:

$$\rho_{im}(\vec{x}, \vec{x}') = \iint d\vec{\eta} d\vec{\eta}' G(\vec{x} - \vec{\eta}) G^*(\vec{x}' - \vec{\eta}') \rho_{ob}(\vec{\eta}, \vec{\eta}') \quad (31)$$

where $G(\vec{x})$ is the coherent point-spread-function (PSF) of the imaging system. The image-AF is therefore

$$A_{im}(\vec{f}, \vec{a}) = \int d\vec{x} \exp(-i2\pi\vec{x}\cdot\vec{f}) \int d\vec{\eta} G(\vec{x} + \vec{a}/2 - \vec{\eta}) \int d\vec{\eta}' G^*(\vec{x} - \vec{a}/2 - \vec{\eta}') \rho_{ob}(\vec{\eta}, \vec{\eta}') \quad (32)$$

By introducing new variables $\vec{\sigma} = (\vec{\eta} + \vec{\eta}')/2$, $\vec{\tau} = \vec{\eta} - \vec{\eta}'$, $\vec{t} = \vec{x} - \vec{\sigma}$ in this integral expression, we obtain directly (Guigay, 1978; Dutta and Goodman, 1977; Ojeda-Castañeda and Sicre, 1984)

$$\begin{aligned} A_{im}(\vec{f}, \vec{a}) &= \iint d\vec{t} d\vec{\sigma} \exp[-i2\pi\vec{f}\cdot(\vec{t} + \vec{\sigma})] \int d\vec{\tau} G\left(\vec{t} + \frac{\vec{a} - \vec{\tau}}{2}\right) G^*\left(\vec{t} - \frac{\vec{a} - \vec{\tau}}{2}\right) \rho_{ob}\left(\vec{\sigma} + \frac{\vec{\tau}}{2}, \vec{\sigma} - \frac{\vec{\tau}}{2}\right) \\ &= \int d\vec{\tau} A_G(\vec{f}, \vec{a} - \vec{\tau}) A_{ob}(\vec{f}, \vec{\tau}) \end{aligned} \quad (33)$$

This is the convolution integral, with respect to the variable $\vec{a}$, of the AF $A_{ob}(\vec{f}, \vec{\tau})$ in the object plane with the function

$$A_G(\vec{f}, \vec{a}) = \int d\vec{x} \exp(-i2\pi\vec{x}\cdot\vec{f}) G\left(\vec{x} + \frac{\vec{a}}{2}\right) G^*\left(\vec{x} - \frac{\vec{a}}{2}\right) = \int d\vec{g} \exp(i2\pi\vec{g}\cdot\vec{a}) \tilde{G}\left(\vec{g} + \frac{\vec{f}}{2}\right) \tilde{G}^*\left(\vec{g} - \frac{\vec{f}}{2}\right) \quad (34)$$

$\tilde{G}(\vec{g})$ is known as the pupil-function of the imaging system. $A_G(\vec{f}, \vec{a})$ is to be considered equivalently as the AF of the coherent PSF or as the pupil-AF.

The image intensity spectrum, which is a quantity of special interest, is obtained by setting $\vec{a}$ equal to 0 in formula (33):

$$\tilde{I}_{im}(\vec{f}) = A_{im}(\vec{f}, \vec{0}) = \int d\vec{\tau} A_G(\vec{f}, -\vec{\tau}) A_{ob}(\vec{f}, \vec{\tau}) \quad (35)$$

Formula (34) shows that, in the particular case of free-space propagation for which $\tilde{G}(\vec{f}) = \exp(-i\pi\lambda D f^2)$, the pupil-AF is a delta-function $\delta(\vec{a} - \lambda D \vec{f})$. The pupil-AF of an ideal (stigmatic) system is equal to $\delta(\vec{a})$.

The AF of the Image of an Incoherent Source

The AF and the WDF of a point-source represented by the Dirac-function $\delta(\vec{x} - \vec{x}_0)$ are respectively

$$A(\vec{f}, \vec{a}) = \int d\vec{x} \exp(-i2\pi\vec{x}\cdot\vec{f}) \delta(\vec{x} - \vec{x}_0 + \vec{a}/2) \delta(\vec{x} - \vec{x}_0 - \vec{a}/2) = \delta(\vec{a}) \exp(-i2\pi\vec{x}_0\cdot\vec{f}) \quad (36)$$

$$W(\vec{x}, \vec{g}) = \int d\vec{a} \exp(-i2\pi\vec{a}\cdot\vec{g}) \delta(\vec{x} - \vec{x}_0 + \vec{a}/2) \delta(\vec{x} - \vec{x}_0 - \vec{a}/2) = \delta(\vec{x} - \vec{x}_0) \quad (37)$$

The AF and the WDF of an extended incoherent source, considered as a continuous distribution $S(\vec{x}_0)$ of mutually incoherent point-sources, are obtained by summing the AF and the WDF of these mutually incoherent point-sources. They are respectively:

$$A(\vec{f}, \vec{a}) = \int d\vec{x}_0 S(\vec{x}_0) \delta(\vec{a}) \exp(-i2\pi\vec{x}_0 \cdot \vec{f}) = \tilde{S}(\vec{f}) \delta(\vec{a}) \quad (38)$$

$$W(\vec{x}, \vec{g}) = \int d\vec{x}_0 S(\vec{x}_0) \delta(\vec{x} - \vec{x}_0) = S(\vec{x}) \quad (39)$$

Derivation of the Zernike-Van Cittert Theorem from the Propagation of the AF

According to formula (24) and (38), at the distance L from the incoherent source, the AF is therefore $\tilde{S}(\vec{f}) \delta(\vec{a} - \lambda L \vec{f})$ and the mutual-intensity can be obtained from formula (9) as

$$\rho(\vec{x} + \vec{a}/2, \vec{x} - \vec{a}/2) = \int d\vec{f} \exp(i2\pi\vec{x} \cdot \vec{f}) \tilde{S}(\vec{f}) \delta(\vec{a} - \lambda L \vec{f}) = \tilde{S}\left(\frac{\vec{a}}{\lambda L}\right) \exp\left(\frac{i2\pi\vec{x} \cdot \vec{a}}{\lambda L}\right) (\lambda L)^{-1} \quad (40)$$

This result, which is the expression of the Van Cittert-Zernike theorem (Born and Wolf, 1999), can also be obtained from the WDF which is equal to $S(\vec{x} - \lambda L \vec{f})$, since the WDF is easily found to be equal to $S(\vec{x})$ in the plane of the incoherent source.

Partial Coherence Properties in the Image of an Incoherent Source (Guigay, 1978)

The image of an incoherent source (or equivalently in the image of an object under incoherent illumination) by a non-ideal optical system shows some degree of coherence because the light from each point of the primary source is spread over a finite area in the image; it is convenient to introduce the image-AF, which characterizes this image completely, including its coherence properties, and has a simple expression:

$$A_{im}(\vec{f}, \vec{a}) = \int d\vec{\tau} A_G(\vec{f}, \vec{a} - \vec{\tau}) \tilde{S}(\vec{f}) \delta(\vec{\tau}) = A_G(\vec{f}, \vec{a}) \tilde{S}(\vec{f}) \quad (41)$$

The Pupil-AF as a Generalization of the OTF

In the case $\vec{a} = 0$, formula (41) gives the image intensity spectrum as

$$\tilde{I}_{im}(\vec{f}) = A_{im}(\vec{f}, \vec{0}) = A_G(\vec{f}, \vec{0}) \tilde{S}(\vec{f}) \quad (42)$$

This formula shows that $A_G(\vec{f}, \vec{0})$ is identical to the well-known Optical Transfer Function (OTF); a detailed account of the OTF can be found in Born and Wolf (1999). Since formula (41) is obviously a generalization of formula (42), the pupil-AF is to be considered as a generalization of the OTF.

The Pupil-AF and the OTF with Defocusing

According to (24), if the image is recorded at a distance D from its normal position (defocusing), $\vec{a}$ is to be replaced by $\vec{a} - \lambda D \vec{f}$ in (41). This means that the defocused pupil-AF is $A_G(\vec{f}, \vec{a} - \lambda D \vec{f})$. The defocused OTF is consequently $A_G(\vec{f}, -\lambda D \vec{f})$. Therefore, the pupil-AF contains the values of the OTF for any value of the defocusing distance. More precisely, as first pointed out in Brenner *et al.* (1983), the pupil-AF can be seen as a polar display of the OTF for variable defocusing distance: the OTF is displayed, as represented schematically in Fig. 1, along lines going through the origin of coordinates in the $(\vec{f}, \vec{a})$ representation (see chapter 5 of Testorf *et al.* (2010) for details).

This connection between the OTF and the pupil-AF has been used (Ojeda-Castañeda and Berriel-Valdos, 1988; Dowski and Cathey, 1995; Fitzgerald *et al.*, 1997; Castro and Ojeda-Castañeda, 2004; Ojeda-Castañeda *et al.*, 2005; Castro *et al.*, 2006; Ojeda-Castañeda and Gómez-Sarabia, 2015) for designing pupil phase-masks (phase apodizers) which increase the depth of focus without losing lateral resolution and light-gathering power. Furthermore, various effects such as the behaviour of the Strehl ratio and the sensitivity to spherical aberration (Ojeda-Castañeda *et al.*, 1987), or the focal shift (Sheppard and Larkin, 2000), have been studied by considerations based on the pupil-AF. These applications are detailed in chapter 10 of Testorf *et al.* (2010).

Phase-Space Tomography

The idea of phase-space tomography (Raymer *et al.*, 1994; Tu and Tamura, 1998; Dragoman *et al.*, 2002; Tran *et al.*, 2005; Liu and Brenner, 2003; Liu *et al.*, 2008) is to reconstruct the AF (or the WDF) in the plane $z=0$ from a set of intensity measurements $I_D(\vec{x})$ in planes at different distances $z=D_n$. The mutual intensity can then be derived from the reconstructed AF (or WDF) by using formula (9). This is of interest for the characterization of the optical field in the plane $z=0$. If an object of transmittance $T(\vec{x})$ is placed in this plane, we obtain

$$\rho_{inc}\left(\vec{x} + \frac{\vec{a}}{2}, \vec{x} - \frac{\vec{a}}{2}\right) T\left(\vec{x} + \frac{\vec{a}}{2}\right) T^*\left(\vec{x} - \frac{\vec{a}}{2}\right) = \int d\vec{f} \exp(i2\pi\vec{f} \cdot \vec{x}) A(\vec{f}, \vec{a}) \quad (43)$$

Fig. 1 Schematic PSO representation. The AF along the line $a = -\lambda Df$ correspond to the intensity spectra $\tilde{I}_D(f)$ at distance D from the reference plane. The integration of formula (44) is to be performed along lines parallel to the f -axis.

where ρ_{inc} is the mutual intensity of the incident beam; with $x=a/2$, this is reduced to

$$\rho_{inc}(\vec{a}, \vec{0}) T(\vec{a}) T^*(\vec{0}) = \int d\vec{f} \exp(i\pi \vec{f} \cdot \vec{a}) A(\vec{f}, \vec{a}) \quad (44)$$

As $\rho_{inc}(\vec{a}, \vec{0})$ and the modulus of $T(\vec{0})$ can be measured independently, this last formula allows the determination (up to a constant phase factor) of the complex function $T(\vec{a})$ from the AF.

The WDF tomographic reconstruction is based on the formula

$$I_D(\vec{x}) = \int d\vec{f} W(\vec{x} - \lambda D \vec{f}, \vec{f}) \quad (45)$$

which shows that $I_D(\vec{x})$ is the projection of the WDF in the $(\vec{x}, \vec{f})$ space along a direction which can be varied by the position $z=D$ of the recording plane. The operation which allows the WDF reconstruction is an inverse Radon transform (Testorf *et al.*, 2010; Tu and Tamura, 1998). The feasibility of the tomographic WDF reconstruction has been discussed in Raymer *et al.* (1994), Tu and Tamura (1998), Dragoman *et al.* (2002), and Tran *et al.* (2005).

The AF reconstruction is considered (Tu and Tamura, 1998; Dragoman *et al.*, 2002; Tran *et al.*, 2005; Liu and Brenner, 2003; Liu *et al.*, 2008) to be simpler, because there is no need of inverse Radon transform (the term phase-space tomography may be considered as inappropriate in this case); we only need to perform the Fourier transformation of the measured $I_D(\vec{x})$; the relation $\tilde{I}_D(\vec{f}) = A(\vec{f}, -\lambda D \vec{f})$ shows that the intensity spectra represent the variations of the AF along the radial lines $\vec{a} = -\lambda D \vec{f}$ in the $(\vec{f}, \vec{a})$ space, as depicted schematically in Fig. 1. In order to sample the AF over the complete $(\vec{f}, \vec{a})$ space, it is necessary to use negative, as well as positive, values of the distance D ; this was not possible previously in X-ray optics because appropriate lenses were not available, but this situation may be changing now, because of the development of the so-called compound refractive X-ray lenses (see Simons *et al.* (2017), Terentyev *et al.* (2017) and references therein).

The process of AF reconstruction was first considered in the case of one-dimensional (1-dim) structures (Tu and Tamura, 1998). A 2-dim structure can be considered as an ensemble of 1-dim y -structures $T(x_0, y)$; the corresponding AF are $A(x_0, f_y, a_y)$, from which $T(x_0, y)$ can be derived as a function of y according to (44). For this purpose, a convenient set-up, actually a 1-Dim propagator system, has been proposed by Liu and Brenner (2003) (see also Liu *et al.* (2008)): a cylindrical lens of focal length F produces an exact image (corresponding to no effective propagation) in the x -direction, while there is propagation over the object-image distance in the y -direction; this distance can be varied by using several cylindrical lenses.

A Possible Approach to AF Reconstruction

Let us consider here the case of a one-dimensional object. The AF in the exit plane of an object illuminated by a tilted plane wave of tilting angle α is

$$\begin{aligned} \int dx \exp(-i2\pi f \cdot x) T\left(x + \frac{a}{2}\right) \exp\left[i2\pi \frac{\alpha}{\lambda} \left(x + \frac{a}{2}\right)\right] T^*\left(x - \frac{a}{2}\right) \exp\left[-i2\pi \frac{\alpha}{\lambda} \left(x - \frac{a}{2}\right)\right] \\ = A_{ob}(f, a) \exp\left(i2\pi \frac{\alpha a}{\lambda}\right) \end{aligned} \quad (46)$$

Fig. 2 Principle of the X-ray analyzer-based imaging system. A quasi-parallel and quasi-monochromatic beam is diffracted, after transmission through the object, by a plate of perfect silicon crystal. The arrangement is such that Bragg diffraction occurs, corresponding to reflecting planes parallel to the crystal surface. The Bragg-diffraction process is highly sensitive to the direction of the rays. Images are recorded across the diffracted beam for different angular settings of the crystal.

where $A_{ob}(f, a)$ is the AF associated to the transmittance $T(x)$. Setting $\omega = \alpha/\lambda$, the intensity spectrum of the image delivered by an imaging system with pupil-AF $A_G(f, \tau)$ is

$$\tilde{I}_{im}(f, \omega) = \int d\tau A_G(f, -\tau) A_{ob}(f, \tau) \exp(i2\pi\omega\tau) \quad (47)$$

which is a Fourier transform. Consequently:

$$A_{ob}(f, \tau) A_G(f, -\tau) = \int d\omega \exp(-i2\pi\omega\tau) \tilde{I}_{im}(f, \omega) \quad (48)$$

Supposing $A_G(f, -\tau)$ to be known and $\tilde{I}_{im}(f, \omega)$ to be measured as a function of ω , this last formula provides the possibility to obtain the object-AF.

This approach has been suggested (Guigay *et al.*, 2007b) in the context of X-ray analyzer-based imaging (ABI) which is a Schlieren-type technique (see Fig. 2) based on X-ray Bragg reflection by a perfect crystal plate (analyzer) placed downstream of the object and acting as an angle selector, therefore as a filter in Fourier space; the Fourier transform of the image amplitude is $\tilde{T}(f)\tilde{G}(f)$, where $\tilde{T}(f)$ is the Fourier transform of the object transmittance and $\tilde{G}(f)$ is the complex reflectivity of the crystal for an incident plane wave having angular shift $\delta\theta = \theta - \theta_B = \lambda f$ with respect to the exact Bragg angle θ_B . $\tilde{G}(f)$ is the pupil-function of the imaging system.

The angular range of Bragg reflection is typically a few microradians. For practical reasons, the beam is fixed and the crystal is rotated. When the crystal is rotated by an angle $\delta\theta$ from its peak position in the incident beam, this pupil-function is changed into $\tilde{G}(f - \delta\theta/\lambda)$. It is easily shown from formula (34) that the pupil-AF $A_G(f, a)$ is then changed into $A_G(f, a)\exp(i2\pi a\delta\theta/\lambda)$; we then obtain for the image intensity spectrum the same formula as (47), with $\omega = \delta\theta/\lambda$.

This technique is sensitive to the object structure in one dimension (sensitive to angular deviations in the Bragg diffraction plane). In order to overcome this limitation, it should be just necessary, for each angular position of the crystal-analyzer, to perform a 90-rotation of the object in its plane, in order to obtain finally two-dim information.

Propagation-Based Holographic Phase Retrieval From Several Images

For the sake of simplicity, let us consider the case of a one-dimensional object in the present section.

Fresnel Diffraction Images as In-Line Holograms

The holographic features of Fresnel diffraction images are clearly shown by considering an object transmittance in the form $T(\eta) = 1 + \psi(\eta)$, which is $\tilde{T}(f) = \delta(f) + \tilde{\psi}(f)$ in Fourier space. Formula (16) can be written as:

$$\begin{aligned} \exp(i\pi\lambda D f^2) \tilde{I}_D(f) &= \int dh \exp(-i2\pi\lambda D h f) [\delta(h+f) + \tilde{\psi}(h+f)] [\delta(h) + \tilde{\psi}^*(h)] \\ \exp(i\pi\lambda D f^2) \tilde{I}_D(f) &= \delta(f) + \tilde{\psi}(f) + \exp(2i\pi\lambda D f^2) \tilde{\psi}^*(-f) + \int dh \exp(-i2\pi\lambda D h f) \tilde{\psi}(h+f) \tilde{\psi}^*(h) \end{aligned} \quad (49)$$

This describes the process of holographic reconstruction. The two first terms corresponds to the reconstructed object; the next term corresponds to the out-of-focus image (at distance $2D$) of the conjugate object and the integral term is negligible if $|\psi(x)| \ll 1$ (weak object). The importance of these perturbation terms can be strongly reduced by performing the following summation based on N images recorded at different distances D_n :

$$\frac{1}{N} \sum_{n=1}^N \tilde{I}_{D_n}(f) \exp(i\pi\lambda D_n f^2) = \delta(f) + \tilde{\psi}(f) + \frac{\tilde{\psi}^*(-f)}{N} \sum_{n=1}^N \exp(2i\pi\lambda D_n f^2) + N^{-1} \int dh \tilde{\psi}(h+f) \tilde{\psi}^*(h) \sum_{n=1}^N \exp(-i2\pi\lambda D_n h f) \quad (50)$$

Fig. 3 Scheme of the set-up for X-ray holotomography operated on the ID19 beamline of the ESRF. The Synchrotron X-ray beam is monochromatised by a crystal monochromator or a multilayer, the energy used being typically around 15 keV (wavelength around 0.08 nm). The sample is mounted on a rotating table. The detector ensemble is a scintillator screen coupled by light optics to a CCD camera. This detector can be moved in order to record images close to the object or at different distances from it.

The quantity on the left-hand side may be calculated from digitally recorded images; this allows a good reconstruction of the object if the perturbation terms are nearly cancelled by this summation procedure.

Application to Phase Retrieval and X-ray Holotomography

In the case of a phase object, such that $T(\eta) = \exp[i(\eta)]$, we obtain

$$\tilde{I}_{D_n}(f) = \delta(f) + 2\sin(\pi\lambda D_n f^2)\tilde{\sim}(f) + (NLD)_n \quad (51)$$

Neglecting the nonlinear term (the integral term) denoted as $(NLD)_n$ in the left-hand side of this equation, the following estimation of the phase spectrum (Cloetens *et al.*, 1999) can be obtained, from the experimentally known $\tilde{I}_{D_n}(f)$ by a least-squares fitting as

$$\tilde{\sim}(f) = \frac{\sum_n \sin(\pi\lambda D_n f^2) \tilde{I}_{D_n}(f)}{2\sum_n \sin^2(\pi\lambda D_n f^2)} \quad (52)$$

From this result, it is possible to calculate the nonlinear terms in order to check whether they could indeed be neglected. If necessary, it is possible to take them into account recursively: the calculated $(NLD)_n$ can be subtracted from the experimentally known $\tilde{I}_{D_n}(f)$ to obtain a new estimate of the phase spectrum

$$\tilde{\sim}(f) = \frac{\sum_n \sin(\pi\lambda D_n f^2) [\tilde{I}_{D_n}(f) - NLT_{D_n}]}{2\sum_n \sin^2(\pi\lambda D_n f^2)} \quad (53)$$

and this process can be continued recursively.

If a single image ($N=1$) was used in formula (43), the phase spectrum could not be obtained for the spatial frequencies f such that transfer function $\sin(\pi\lambda D f^2)$ is close to 0. Using several images (typically 4 or 5 images) allows to eliminate this defect and to reduce the influence of the nonlinear terms.

This phase retrieval approach, which has some similarity with the focus variation method used in electron microscopy (Op de Beeck *et al.*, 1996), has been implemented in Synchrotron X-ray optics (see Fig. 3) to provide two-dimensional phase maps, with micrometer resolution, of objects showing a nearly uniform absorption but introducing an important phase modulation; advantage is taken from the high degree of spatial coherence (due to the small lateral size of the source and the long source-specimen-distance) and the good monochromaticity available on modern Synchrotron beamlines using crystal or multilayer monochromators. The phase maps obtained for different orientations of the object are used as input for a tomographic reconstruction of the three-dimensional distribution of the electron density in the sample. This technique named holotomography (Guigay *et al.*, 2007a; Cloetens *et al.*, 1999; Zabler *et al.*, 2005) is of particular interest in the case of objects opaque to visible light. It has been successfully applied to a large variety of objects of interest in biological or material sciences. For a particular recent application, see Mocella *et al.* (2015).

Conclusion

The AF shares with the WDF the ability to describe the propagation of a partially coherent beam in free space and through a paraxial optical system in a simple and elegant way. The AF is a generalization of the intensity spectra which are the basis of important phase retrieval methods. The images given by a space-invariant system are conveniently described in terms of AF of the object and of the pupil-AF which is a generalization of the OTF and has important applications in the design of phase apodizers.

Phase-space tomography is a growing field of research, in which the AF tomographic reconstruction may be more practical than the WDF tomographic reconstruction.

Phase Space Tomography in Optics

Introduction

Tomographic techniques in a wide sense consist in the reconstruction of a n – dimensional (nD) object from a set of data of lower, usually $(n - 1)$, dimension. They are widely applied in medicine and technology for noninvasive inspection of internal structure of macro- and microorganisms and other 3D samples. There exist different approaches developed in optics to obtain this valuable information: computed tomography (CT), optical diffraction tomography, optical coherence tomography, to name the most known ones. Phase space tomography (PST) is intrinsically different from the mentioned tomographic modalities, because it does not directly serve for the tomographic analysis of the sample structure. Meanwhile it is focused on the tomographic study of the light beam itself. From mathematical point of view the PST is closer to the CT technique since both of them are based on the rotation of the object under inspection and measuring a set of its projections. However, the object of reconstruction in the CT and the PST are completely different. In the case of the CT it is the distribution of the absorption coefficient of a physically existed 3D object. While in the case of the PST the object is the Wigner distribution function (WD) which describes coherence properties of classical light (Bastiaans, 2008) or defines a quantum state (density matrix) of light source in quantum systems (D'Ariano *et al.*, 2003). Neither the light coherence characteristics nor density matrix can be measured directly. This information, required for the development of imaging techniques, telecommunication protocols, quantum computing methods, etc., is possible to recover applying the PST tools. The WD is a real function but it can take negative values that impedes its direct measurements. Nevertheless, the projections of the WD are always non-negative and are associated with measurable quantities. This fact together with rotation of the WD after light propagation through certain optical systems described by canonical integral transforms form the basis of the PST (Raymer *et al.*, 1994). Measuring a proper set of the WD projections and using the inverse Radon transform, or other tomography reconstruction algorithm, the WD, and therefore the related beam characteristics are obtained. Below the application of the PST for the analysis of spatial structure of optical beams, short pulses and quantum states are considered.

Light Beam Characterization

Let us consider a linearly polarized optical beam propagated in z direction. The only quantity which can be measured directly is its time-averaged intensity distribution, because the oscillations of the electromagnetic field are too fast for any currently available detectors. However, from the knowledge of the intensity distribution $I(\mathbf{r})$ in a certain plane $z=z_1$ (here we have defined a 2D position vector $\mathbf{r}=[x,y]^t$ at the xy plane transverse to the propagation direction z , where the superscript t denotes the transposition operation) it is impossible to predict the value of $I(\mathbf{r})$ in other plane $z=z_2$ or to describe the beam interaction with a sample under study. In order to do this in the case of quasi-monochromatic coherent beam we need to know its complex field amplitude $f(\mathbf{r})=a(\mathbf{r})\exp[i\varphi(\mathbf{r})]$, where $a(\mathbf{r})$ and $\varphi(\mathbf{r})$ referred to as amplitude and phase are real valued. In this case $I(\mathbf{r})=|f(\mathbf{r})|^2=a^2(\mathbf{r})$ and therefore the amplitude $a(\mathbf{r})$ can be easily measured $a(\mathbf{r})=\sqrt{I(\mathbf{r})}$ using, for example, a digital camera while the determination of the phase $\varphi(\mathbf{r})$ requires some special interferometric or iterative techniques. However, in the most cases light is not fully coherent and its phase is stochastically varying. The description of such partially coherent light requires the application of statistical methods. Often it is assumed that light follows Gaussian statistics and therefore is described by two-point correlation function $\Gamma(\mathbf{r}_1, \mathbf{r}_2)=\langle f(\mathbf{r}_1)f^*(\mathbf{r}_2) \rangle$ known as mutual intensity (MI) (Goodman, 2000). Here $\langle \cdot \rangle$ stands for ensemble averaging which for ergodic process can be substituted by time averaging. The MI is a non-negative definite Hermitian function of four variables $\Gamma(\mathbf{r}_1, \mathbf{r}_2)=\Gamma^*(\mathbf{r}_2, \mathbf{r}_1)$. Note that only the values $\Gamma(\mathbf{r}, \mathbf{r})=\langle |f(\mathbf{r})|^2 \rangle$, corresponding to the intensity distribution, can be directly measured. For the polychromatic light, similar expression known as cross-spectral density, corresponding to the temporal Fourier transform of the mutual coherence function is used for beam description. The MI gauges the field correlation at the points $\mathbf{r}_1$ and $\mathbf{r}_2$ via complex coherence factor (Goodman, 2000): $\gamma(\mathbf{r}_1, \mathbf{r}_2)=\Gamma(\mathbf{r}_1, \mathbf{r}_2)/\sqrt{\Gamma(\mathbf{r}_1, \mathbf{r}_1)\Gamma(\mathbf{r}_2, \mathbf{r}_2)}$.

Instead of the MI, its Fourier transform (FT) with respect to the position difference $\mathbf{r}'=\mathbf{r}_1-\mathbf{r}_2$, known as Wigner distribution (WD) (Bastiaans, 2008)

$$W(\mathbf{r}, \mathbf{p}) = \frac{1}{\sigma^2} \int d\mathbf{r}' \Gamma\left(\mathbf{r} - \frac{\mathbf{r}'}{2}, \mathbf{r} + \frac{\mathbf{r}'}{2}\right) \exp\left(-\frac{i2\pi}{\sigma^2} \mathbf{p}' \mathbf{r}'\right) \quad (1)$$

or the FT with respect to $\mathbf{r}=(\mathbf{r}_1+\mathbf{r}_2)/2$ known as Ambiguity function (AF)

$$A(\mathbf{r}', \mathbf{p}) = \frac{1}{\sigma^2} \int d\mathbf{r} \Gamma\left(\mathbf{r} - \frac{\mathbf{r}'}{2}, \mathbf{r} + \frac{\mathbf{r}'}{2}\right) \exp\left(-\frac{i2\pi}{\sigma^2} \mathbf{p}' \mathbf{r}\right) \quad (2)$$

can be used for beam description. Here $\mathbf{p}=[u,v]^t=\sigma^2\mathbf{k}_\perp$ is a vector proportional to the transverse projection of the spatial frequency vector, $\mathbf{k}_\perp$, and σ is a convenient constant with units of length that is commonly used in Fourier optics. The WD of 2D field is a real valued function of four Cartesian coordinates (x, y, u, v) , which form so called phase space. It follows from the Eqs. (1–2) that the MI can be recovered from the WD (or the AF) applying the inverse FT

$$\begin{aligned}\Gamma(\mathbf{r}_1, \mathbf{r}_2) &= \frac{1}{\sigma^2} \int d\mathbf{p} W\left(\frac{\mathbf{r}_1 + \mathbf{r}_2}{2}, \mathbf{p}\right) \exp\left(\frac{i2\pi}{\sigma^2} \mathbf{p}^t (\mathbf{r}_1 - \mathbf{r}_2)\right) \\ &= \frac{1}{\sigma^2} \int d\mathbf{p} A(\mathbf{r}_1 - \mathbf{r}_2, \mathbf{p}) \exp\left(\frac{i2\pi}{\sigma^2} \mathbf{p}^t (\mathbf{r}_1 + \mathbf{r}_2)\right)\end{aligned}\quad (3)$$

Moreover, if the light is completely coherent, $I(\mathbf{r}_1, \mathbf{r}_2)=1$ and $\Gamma(\mathbf{r}_1, \mathbf{r}_2)=f(\mathbf{r}_1)f^*(\mathbf{r}_2)$, then the phase of the complex field amplitude up to the constant φ_0 can be obtained from the MI

$$\varphi(\mathbf{r}) = \varphi_0 + \arg[\Gamma(\mathbf{r}, \mathbf{r}_0)] \quad (4)$$

where $\mathbf{r}_0$ is a point in which the field intensity is not zero. Note that the phase information is very demanded, for example, in optical metrology and quantitative microscopy.

PST Fundamentals

Actually developed detectors allow measuring only beam intensity distribution and therefore no one of the mentioned functions, MI, WD and AF, can be measured directly: the MI and AF are complex valued functions, while the WD is real but takes non-negative values only in the case of coherent Gaussian beam. Nevertheless, the projection of the WD on the (x, y) – plane corresponds to the beam intensity distribution

$$I(\mathbf{r}) = \frac{1}{\sigma^2} \int d\mathbf{p} W(\mathbf{r}, \mathbf{p}) \quad (5)$$

and therefore is measurable. On the other side the intensity distribution is the FT of the AF slice

$$I(\mathbf{r}) = \frac{1}{\sigma^2} \int d\mathbf{p} A(0, \mathbf{p}) \exp\left(\frac{i2\pi}{\sigma^2} \mathbf{p}^t \mathbf{r}\right) \quad (6)$$

The PST method based on the recovery of the AF is considered, for example, in Cámara *et al.* (2014), Tran *et al.* (2005), and Tu and Tamura (1997).

In order to apply the PST method for beam characterization the WD (or the AF) has to be rotated and a set of corresponding projections have to be measured. In paraxial approximation the beam propagation through a first-order optical system – an optical system composed by centered spherical and cylindrical lenses and/or mirrors separated by homogeneous medium – is described by the 2D linear canonical integral transform $f_T(\mathbf{r}_o) = \int K_T(\mathbf{r}_i, \mathbf{r}_o) f(\mathbf{r}_i) d\mathbf{r}_i$ where $f(\mathbf{r}_i)$ and $f_T(\mathbf{r}_o)$ are the complex field amplitude in the input and output planes of the system and

$$K_T(\mathbf{r}_i, \mathbf{r}_o) = \frac{1}{\sigma^2 \sqrt{\det(i\mathbf{B})}} \exp\left[\frac{i\pi}{\sigma^2} (\mathbf{r}_o^t \mathbf{D} \mathbf{B}^{-1} \mathbf{r}_o - 2\mathbf{r}_i^t \mathbf{B}^{-1} \mathbf{r}_o + \mathbf{r}_i^t \mathbf{B}^{-1} \mathbf{A} \mathbf{r}_i)\right] \quad (7)$$

for $\det \mathbf{B} \neq 0$ and

$$K_T(\mathbf{r}_i, \mathbf{r}_o) = \frac{1}{\sqrt{|\det \mathbf{A}|}} \exp\left[\frac{i\pi}{\sigma^2} \mathbf{r}_o^t \mathbf{C} \mathbf{A}^{-1} \mathbf{r}_o\right] \delta(\mathbf{r}_i - \mathbf{A}^{-1} \mathbf{r}_o) \quad (8)$$

for $\mathbf{B}=\mathbf{0}$. Here $\mathbf{A}$, $\mathbf{B}$, $\mathbf{C}$ and $\mathbf{D}$ are 2×2 sub-matrices of the 4×4 dimensionless ray transformation matrix $\mathbf{T}$, which provides the relation between the position $\mathbf{r}$ and direction (proportional to $\mathbf{p}$) of the ray in the input ($\mathbf{r}_i$ and $\mathbf{p}_i$) and output ($\mathbf{r}_o$ and $\mathbf{p}_o$) planes of an optical system:

$$\begin{bmatrix} \mathbf{r}_o \\ \mathbf{p}_o \end{bmatrix} = \begin{bmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{bmatrix} \begin{bmatrix} \mathbf{r}_i \\ \mathbf{p}_i \end{bmatrix} = \mathbf{T} \begin{bmatrix} \mathbf{r}_i \\ \mathbf{p}_i \end{bmatrix} \quad (9)$$

Note, that for the matrix describing the linear ray propagation in free space

$$\mathbf{T}_z = \begin{bmatrix} \mathbf{I} & \frac{z}{\lambda} \mathbf{I} \\ \mathbf{0} & \mathbf{I} \end{bmatrix} \quad (10)$$

where $\mathbf{I}$ is a unity matrix, λ is the wavelength and z is the distance between the input and output planes, the expression Eq. (7) with $\sigma=\lambda$ is reduced to the kernel of the Fresnel transform. Meanwhile the matrix

$$\mathbf{T}_L = \begin{bmatrix} \mathbf{I} & \mathbf{0} \\ \mathbf{C} & \mathbf{I} \end{bmatrix} \quad (11)$$

corresponds to spherical/cylindrical thin lens or mirror action yielding to quadratic phase modulation of the wavefield according to the Eq. (8) with $\sigma=\lambda$. For example, the sub-matrix $\mathbf{C} = \begin{bmatrix} -\lambda f_x^{-1} & 0 & 0 & -\lambda f_y^{-1} \end{bmatrix}$ describes the orthogonal superposition of two

convergent cylindrical lenses with front focal distances f_x and f_y , that for $f_x = f_y$ corresponds to the spherical lens. Two assembled cylindrical lenses with transverse axes forming any other angle, called *generalized lens*, is associated with symmetric sub-matrix $C = [c_{xx}, c_{xy}; c_{xy}, c_{yy}]$. Using a set of cylindrical lenses and choosing appropriate distances between them optical system performing any 2D canonical integral transform can be constructed.

The WD, $W_T(\mathbf{r}, \mathbf{p})$, of the beam at the output plane of a first-order system described by the ray transformation matrix $T = [A, B; C, D]$, is related to the WD at the input plane, $W(\mathbf{r}, \mathbf{p})$, by an affine transformation (Bastiaans, 2008)

$$W_T(\mathbf{r}, \mathbf{p}) = W(D^t \mathbf{r} - B^t \mathbf{p}, -C^t \mathbf{r} + A^t \mathbf{p}) \quad (12)$$

which, in general, includes rotation, shearing and scaling in phase space. Similar expression is valid for the AF

$$A_T(\mathbf{r}, \mathbf{p}) = A(D^t \mathbf{r} - B^t \mathbf{p}, -C^t \mathbf{r} + A^t \mathbf{p}) \quad (13)$$

In particular, the rotations in phase space, which are described by the ray transformation matrix T_R with parameters $A = D$ and $B = -C$, are needed to apply the PST method. There are two principle kind phase space rotators: the fractional Fourier transform (FrFT) (Ozaktas et al., 2001) associated with the matrix $T_{FrFT}(\alpha_x, \alpha_y)$ defined by

$$\begin{aligned} A_{FrFT} &= D_{FrFT} = \begin{bmatrix} \cos \alpha_x & 0 \\ 0 & \cos \alpha_y \end{bmatrix} \\ B_{FrFT} &= -C_{FrFT} = \begin{bmatrix} \sin \alpha_x & 0 \\ 0 & \sin \alpha_y \end{bmatrix} \end{aligned} \quad (14)$$

which describes the WD rotation in the planes xu and yv for angles $\alpha_{x,y}$ respectively, and image rotator (IR) associated with the matrix $T_{IR}(\beta)$ defined by

$$A_{IR} = D_{IR} = \begin{bmatrix} \cos \beta & \sin \beta \\ -\sin \beta & \cos \beta \end{bmatrix} \text{ and } B_{IR} = C_{IR} = 0 \quad (15)$$

which corresponds to the simultaneous WD rotation in xy and uv for angle β . Their combination defines any other phase space rotator associated with $T_R(\gamma, \alpha_x, \alpha_y, \beta) = T_{IR}(\gamma) T_{FrFT}(\alpha_x, \alpha_y) T_{IR}(\beta)$. Note that for the PST applications the parameter γ is irrelevant since it describes the rotation of the coordinate system in the output xy plane. The intensity distribution in the output plane of a phase space rotator corresponds to the WD projection given by

$$I_{T_R}(\mathbf{r}) = \langle |f_{T_R}(\mathbf{r})|^2 \rangle = \frac{1}{\sigma^2} \int d\mathbf{p} W_{T_R}(\mathbf{r}, \mathbf{p}) = \frac{1}{\sigma^2} \int d\mathbf{p} W(D_R^t \mathbf{r} - B_R^t \mathbf{p}, -C_R^t \mathbf{r} + A_R^t \mathbf{p}) \quad (16)$$

For complete WD recovery using the inverse Radon transform, or other tomography reconstruction algorithm a set of 2D projections $\{I_{T_R}(\mathbf{r})\}$ for two independent angles (both covering a π -interval) associated with the rotation in two orthogonal planes of the phase space is needed. Initially the PST method was established for the projection set corresponding to the FRFT, $T_R(0, \alpha_x, \alpha_y, 0) = T_{FrFT}(\alpha_x, \alpha_y)$ (Raymer et al., 1994) while in Cámara (2015) and Cámara et al. (2013) it has been shown that the phase space rotator described by $T_R(0, 0, \alpha, \beta)$ or by $T_R(0, \alpha, 0, \beta)$ with

$$\begin{aligned} A_R(0, \alpha, 0, \beta) &= \begin{bmatrix} \cos \alpha \cos \beta & \cos \alpha \sin \beta \\ -\sin \beta & \cos \beta \end{bmatrix} \\ B_R(0, \alpha, 0, \beta) &= \begin{bmatrix} \sin \alpha \cos \beta & \sin \alpha \sin \beta \\ -\sin \beta & \cos \beta \end{bmatrix} \end{aligned} \quad (17)$$

can be applied.

While the theoretical fundamentals of the PST method seem straightforward its experimental realization is rather difficult since real-world applications require fast acquisition and processing of the experimental data together with comprehensive analysis of the resulting four-dimensional functions associated to the light coherence information. Any a priori information about a studied beam can simplify the task and decrease the number of projections required for WD reconstruction. Some methods assume certain hypothesis about field model (Tian et al., 2012), its symmetry (Agarwal and Simon, 2000; Alieva et al., 2011; Cámara, 2015; Cámara et al., 2014) or coherence homogeneity. Below two schemes for practical realization of the PST analysis of the beam coherence state in the absence of a priori information are considered.

PST for 1D Beam Characterization

The application of the PST for beam analysis meets inherent difficulty caused by the high dimension of the WD and related functions. It yields to the excessive computation effort to process the measured data (WD projections) into the requested result (the WD, AF or MI). One of solutions of this complex problem is to decompose a 2D beam into 1D signals and recover their WDs. In order to select a 1D signal a thin slit is usually used. This mask has to be moved and rotated in the xy input plane in order to

explore consequently the beam coherence properties along the corresponding lines. The WD of a selected 1D signal described by the complex field amplitude $f(x)$ is a 2D function, $W(x, u)$, that can be easily presented graphically and analyzed. In the associated 2D phase space xu there is only one phase space rotator: the 1D FrFT whose the kernel is written as

$$K_\alpha(x_i, x) = \frac{1}{\sigma \sqrt{i \sin \alpha}} \exp \left[\frac{i\pi (x^2 + x_i^2) \cos \alpha - 2xx_i}{\sin \alpha} \right] \quad (18)$$

The 1D FrFT produces the rotation of the WD

$$W_\alpha(x, u) = W(x \cos \alpha - u \sin \alpha, x \sin \alpha + u \cos \alpha) \quad (19)$$

Measuring the WD projections

$$P_\alpha(x) = \frac{1}{\sigma} \int du W(x \cos \alpha - u \sin \alpha, x \sin \alpha + u \cos \alpha) \quad (20)$$

for angles covered a π -interval $\alpha \in [0, \pi]$ which corresponds to the Radon transform of the WD (also called as Radon-Wigner transform) the $W(x, u)$ can be reconstructed applying, for example, the filtered back-propagation algorithm

$$W(x, u) = \frac{1}{\sigma^2} \int_0^\pi \int dx d\rho |P_\alpha(\rho)| \exp \left[-\frac{2\pi}{\sigma^2} \rho (x \cos \alpha - u \sin \alpha) \right] \quad (21)$$

If the projections are available for the interval $\alpha \in [\alpha_0, \alpha_0 + \pi]$ then the WD, $W(x \cos \alpha_0 - u \sin \alpha_0, x \sin \alpha_0 + u \cos \alpha_0)$ reconstructed by this expression (the integration limits in this case are from α_0 to $\alpha_0 + \pi$) is rotated at angle α_0 with respect to one, $W(x, u)$, described the input signal. The MI is obtained correspondingly as

$$\Gamma(x_1, x_2) = \frac{1}{\sigma} \int du W\left(\frac{x_1 + x_2}{2}, u\right) \exp\left(\frac{i2\pi}{\sigma^2} u(x_1 - x_2)\right) \quad (22)$$

The principal advantage of this method is a possibility to registered in one shot all required projections of the $W(x, u)$ in the digital camera display. For this purpose a 1D signal is converted into a 2D one, which is its multiple-copy and varifocal lenses or Fresnel zone plates are applied to perform the FrFT of every copy for different angle. Several designs for such system, known as Radon-Wigner display (RWD), have been proposed (Cámara *et al.*, 2011; Granieri *et al.*, 1997; Mendlovic *et al.*, 1996). One of them is discussed below. While this method is suitable for analysis of 1D optical signals it has important drawbacks when it is applied for the 2D beams. The slit mask application introduces artifacts. The conversion of 1D signal into a 2D one produces significant power reduction of the analyzed field and therefore decreases the signal to noise ratio. For analysis of the beam coherence properties along another line of xy plane the displacement and/or rotation of the slit mask and the RWD are required.

PST for 2D Beam Characterization

Another approach for practical application of the PST is based on an appropriate choice of the projections set and the order of their acquisition. As it was mentioned above several projection sets can be used for the reconstruction of the 4D-WD. As well as for the tomographic analysis of horizontal slices of the 3D object it is beneficial rotate the object along the vertical axes, there exists the 4D-WD projection set which is more appropriate for the beam coherence analysis. This set, hereinafter referred as $\{P_{\alpha, \beta}(\mathbf{r})\}$, is obtained by rotating the WD in the xy and xu planes for angles β and α , respectively (phase space rotator described by the ray transformation matrix $T_R(0, \alpha, 0, \beta)$) (Cámara, 2015; Cámara *et al.*, 2013).

The projection set $\{P_{\alpha, \beta}(\mathbf{r})\}$, comprises several subsets, $\{P_{\alpha, \beta_0}(\mathbf{r})\}$, defined by fixing $\beta = \beta_0$, which are acquired consecutively. Each subset provides the information about field correlation at whichever points $\mathbf{r}_1$ and $\mathbf{r}_2$ that are contained in a line which forms an angle β_0 with axes x . The MI at such a line is defined as $\Gamma_{\beta_0}(\mathbf{r}_0, s) = \Gamma(\mathbf{r}_0, \mathbf{r}_0 + s\mathbf{n})$, where $\mathbf{r}_0$ is the reference point, $\mathbf{n} = [\cos \beta_0, \sin \beta_0]^T$ and s are the direction and running coordinate of the line, respectively. For example, from one slice of the projection subset $\{P_{\alpha, 0}([x, y_0]^T)\}$ for any value of y_0 (see Fig. 1) the 2D-WD, $W(x, u; y_0)$, of the 1D signal $f(x; y_0)$ is obtained using the Eq. (21), where

Fig. 1 Scheme explaining the parallel data processing for WD reconstruction. The Wigner distribution $W(x, u; y_0)$ of the field along a chosen line $y = y_0$ is reconstructed for each projection subset slice defined by both β_0 and y_0 (see, e.g., the blue slice). Note that the Wigner distribution takes positive and negative values (white color indicates zero level).

$P_\alpha(\rho) = P_{\alpha,0}([\rho, \gamma_0]^t)$. The correlation function for the field at reference point $\mathbf{r}_0 = [x_0, \gamma_0]^t = \mathbf{r}_1$ and any other point $\mathbf{r}_2 = \mathbf{r}_0 + s[1, 0]^t$ contained in the horizontal line $\gamma = \gamma_0$ is then calculated as

$$\Gamma_0(\mathbf{r}_0, s) = \frac{1}{\sigma} \int du W(x_0 + s/2, u; \gamma_0) \exp\left(\frac{i2\pi}{\sigma^2} su\right) \quad (23)$$

Note that from the same subset $\{P_{\alpha,0}([x, \gamma]^t)\}$ the MI for any two points contained in the same horizontal line ($\gamma = \text{constant}$) is obtained. To find the coherence relations for two points with different γ coordinates, one has to perform the rotation in the xy plane for the corresponding angle β_0 and to repeat the procedure described above using the projection subset $\{P_{\alpha,\beta_0}(\mathbf{r})\}$. Doing this, we recover the desired information about field correlation avoiding the reconstruction of the entire 4D-WD and its posterior processing as it needed, for example, if the projection set corresponding to 2D-FrFT ($T_R(0, \alpha_x, \alpha_y, 0) = T_{FrFT}(\alpha_x, \alpha_y)$) is used. Although the amount of data required for full beam characterization is the same as in other realizations of the PST, this choice of projection set, $\{P_{\alpha,\beta}(\mathbf{r})\}$, brings powerful benefits: (1) The data acquisition and processing tasks are performed simultaneously since every projection subset is an independent entity. (2) As one projection subset slice is independent of the rest, parallel computing can be used for the data processing. (3) Physically meaningful information is obtained from a reduced number of projections that allows starting the beam analysis before the complete projection set is acquired.

Optical Setups for PST

Several experimental phase space rotators described by ray transformation matrix T_R have been proposed. All of them are based on a combination of lens (or other optical elements producing quadratic phase modulation of wavefield) separated by the free space intervals. Since only the intensity distribution is measured then the phase in the output plane of the optical system applied for the PST can be arbitrary. This allows increasing a number of suitable setups and often simplifying their design. Indeed the intensity distributions in the output of the systems described by the ray transformation matrices $T_L T_R$ and T_R coincide and depend only on T_R . The scanning of the rotation angles is achieved by modification of the lens powers or distances between them. However, the insert of a lens or change of the distance usually require the system alignment that is incompatible for a fast projection acquisition required for the practical application of the PST. Moreover, for accurate WD reconstruction it is recommended to avoid the projection re-scaling. All these conditions can be fulfilled if digital lenses implemented by spatial light modulator (SLM) are used. Indeed the phase-only SLM easily performs a quadratic phase wavefront modulation that is an action of a thin lens. This allows designing an optical setup with all elements located in fixed position and a programmable control of the projection parameters. In this case the speed of the projection acquisition is limited by the SLM and digital camera (usually video rate).

Different projections sets including ones discussed above (corresponding to $T_R(0, \alpha_x, \alpha_y, 0)$ and $T_R(0, \alpha, 0, \beta)$) can be automatically acquired using the programmable optical setup (Cámara *et al.*, 2013; Rodrigo *et al.*, 2009) shown in Fig. 2. The setup comprises two generalized lenses implemented by two SLMs and a digital camera. The distance z between every two consecutive elements is fixed. Specifically, for acquisition the projection set $\{P_{\alpha,\beta}(\mathbf{r})\}$ these lenses L_j ($j=1,2$) have the following transmission functions

$$L_j(x, y) = \exp\left[-i\pi \frac{(x \cos \beta + y \sin \beta)^2}{\lambda f_j}\right] \exp\left[-i\pi \frac{(-x \sin \beta + y \cos \beta)^2}{\lambda g_j}\right] \quad (24)$$

where the focal lengths are $f_1 = 2z/(2 - \cot(\alpha/2))$, $f_2 = z/(2 - 2 \sin \alpha)$ and $g_1 = z$, $g_2 = z/2$, are given as a function of the transformation angle $\alpha \in [\pi/2, 3\pi/2]$. This setup is described by the matrix $T_L T_R(-\beta, \alpha, 0, \beta)$. Then the intensity distribution in its output plane is equal to one corresponding to the desired transformation $T_R(0, \alpha, 0, \beta)$ except for a rotation at an angle $-\beta$. To compensate this effect and obtain the corresponding WD projection the image acquired by the digital camera has to be rotated an angle β that can be easily performed digitally. The number of the acquired projections which is one of the principle parameters defining the resolution of the WD reconstruction can easily reach a value 180 per one subset $\{P_{\alpha,\beta_0}(\mathbf{r})\}$.

The varifocal lens needed for RWD implementation can also be realized by the SLM (Cámara, 2015; Cámara *et al.*, 2011). An illustration of such system is displayed in Fig. 3. It consists in two SLMs separated a fixed distance z , and two cylindrical lenses of

Fig. 2 Scheme of a programmable setup for complete WD projection set acquisition, required for the WD reconstruction. For every β and α the SLM₁ and SLM₂ implement generalized lenses L_1 and L_2 , respectively, given by Eq. (24).

Fig. 3 Scheme of a programmable Radon Wigner display using spatial light modulators. SLMs implement N 1D lenses described by Eqs. (25)–(26).

focal length $z/4$ with phase modulation in the y direction also separated a fixed distance z . N copies of the input 1D signal $f(x)$ arranged in set of N vertical channels are projected into input plane of the RWD, which coincides with the position of the first SLM. The SLMs implement the multichannel phase masks. Each channel of the phase mask is programmed to perform the 1D-FrFT operation for an arbitrary angle in the range $\alpha \in [\pi/2, 3\pi/2]$. In order to acquire the full-range WD projections for N equidistant angles, the n th channel of the j th SLM implements the transmission function $L_j(x, n)$ given by:

$$L_1(x, n) = \exp \left[-i\pi \frac{x^2}{\lambda z} \left(1 - \frac{1}{2} \cot \frac{\alpha_n}{2} \right) \right] \quad (25)$$

$$L_2(x, n) = \exp \left[-i2\pi \frac{x^2}{\lambda z} (1 - \sin \alpha_{N-n+1}) \right] \quad (26)$$

where $n = 1, \dots, N$ and $\alpha_n = \pi/2 + (n-1)/N\pi$ is the FrFT angle associated with the j th channel. While the SLMs perform the FrFT in the x direction, the glass cylindrical lenses compensate the beam propagation in the y direction by imaging the first SLM into the second, and the second into the output plane. Since the first cylindrical lens inverts the channel position, the n th channel of the second SLM implements the angle labeled by $N - n + 1$ in Eq. (26). At the output plane, placed at a distance $z/2$ from the last cylindrical lens, a digital camera registers in one shot all required WD projections of the input 1D signal. The number of channels and therefore the WD projections depend on the size of the SLM and camera displays and can easily reach $N=300$ if the 2D expansion of the 1D signal is energetically resolved.

Chronocyclic Tomography for Optical Pulse Characterization

We have considered the application of the phase space tomography for characterization of the spatial light coherence, meanwhile it also can be used for the analysis of short optical pulses (Beck *et al.*, 1993; Dorrer and Kang, 2003). In this case the time t and temporal frequency ν are coordinates of the phase space and the method of the corresponding WD recovery is called chronocyclic tomography. The electrical field of an optical pulse is described by

$$E(t) = |E(t)| \exp[i\phi_t(t)] \exp(-i2\pi\nu_0 t) \quad (27)$$

where $|E(t)|$ and $\phi_t(t)$ are the time-dependent pulse envelop and phase correspondingly and ν_0 is the carrier frequency. The instantaneous power $|E(t)|^2$ can be measured only if the pulse duration is sufficiently larger than the response time of the photodetector. Alternatively the pulse can be described in frequency domain as $\tilde{E}(\nu) = |\tilde{E}(\nu)| \exp[i\phi_\nu(\nu)]$, where $\tilde{E}(\nu)$ is a FT of the $E(t)$, $\phi_\nu(\nu)$ is a spectral phase. The spectral density $|\tilde{E}(\nu)|^2$ can be easily measured by a spectrometer. Usually an ensemble of pulses are involved in the experiments and its statistical properties, in particular, two-time correlation function $\Gamma(t_1, t_2) = \langle E(t_1) E^*(t_2) \rangle$ or the related WD

$$W(t, \nu) = \eta \int dt' \Gamma(t - t'/2, t + t'/2) \exp(-i2\pi t' \nu) \quad (28)$$

are of interest. Here η is a convenient constant with units of frequency. If all pulses are identical then the amplitude and the phase of $E(t)$ up to the constant factor can be retrieved from $\Gamma(t_1, t_2)$.

As well as in the spatial PST case the devices which produce the rotation of the WD, $W(t, \nu)$, are needed for chronocyclic tomography. A quadratic temporal phase modulator and the propagation in dispersive medium or two-grating compressor (quadratic spectral phase modulation) are the analogues of lens and Fresnel propagator, respectively. After pulse propagation through a temporal fractional FT system constructed by such devices, whose parameters control the rotation angle α , the required number of the WD projections $P_\alpha(\nu) = \eta \int W(t\eta^2 \cos \alpha + \nu \sin \alpha, \nu \cos \alpha - t\eta^2 \sin \alpha) dt$ can be registered by a spectrometer. Then the WD (and therefore the two-point correlation function $\Gamma(t_1, t_2)$) is reconstructed applying, for example, the inverse Radon transform.

PST for Quantum Light Characterization

In quantum optics, light is described by the concept of *photons* which are light particles with a particular energy (frequency), polarization, and wave vector (direction of propagation). In the classical textbooks where the second quantization is derived (D'Ariano *et al.*, 2003), photons have a plane-wave spatial structure. However, it is easy to imagine photons with a general transverse structure just by assuming a superposition of plane-wave photons (Calvo *et al.*, 2006). Hence, these quantum entities can be well localized both in space and time.

Many quantum information and quantum computation protocols exploit high-dimensional Hilbert spaces. Photons, which constitute the main carrier of information between nodes of quantum networks, can store high-dimensional quantum bits in their spatial degrees of freedom. These degrees of freedom can be tailored by resorting to the symplectic invariant approach based on lossless linear canonical transformations introduced before in the context of classical optics, Eqs. (7–8). These transformations enable one to manipulate the transverse structure of a single photon prepared in superpositions of paraxial modes. Before describing those transformations acting on photons, it is suitable at this stage to introduce in a nutshell the concept of a photon in the paraxial approximation.

In quantum electrodynamics the photon is interpreted as an excitation of the quantized mode field (D'Ariano *et al.*, 2003). Within this quantization, we can define a set of creation and annihilation operators: those that create a photon from the vacuum with a certain paraxial transverse profile, for example, with a well-defined Laguerre-Gaussian mode or a Hermite-Gaussian mode. The most general (paraxial) single-photon pure state can be described as (Calvo *et al.*, 2006)

$$|\psi\rangle = \sum_{\sigma, n_x, n_y} \int_0^\infty d\omega C_{\sigma, n_x, n_y}(\omega) \hat{b}_{\sigma, n_x, n_y}^\dagger(\omega) |vac\rangle \quad (29)$$

Here, $\hat{b}_{\sigma, n_x, n_y}^\dagger(\omega)$ denotes the bosonic creation operator of a photon with a Hermite-Gaussian mode (n_x, n_y) , a linear polarization σ , and a frequency ω acting on the vacuum state $|vac\rangle$. The commutation relations read as $[\hat{b}_{\sigma, n_x, n_y}(\omega), \hat{b}_{\sigma', n_x', n_y'}^\dagger(\omega')] = \delta_{\sigma\sigma'} \delta_{n_x n_x'} \delta_{n_y n_y'} \delta(\omega - \omega')$. The complex coefficients $C_{\sigma, n_x, n_y}(\omega)$ can be interpreted as the probability amplitudes for finding a photon in the state $\hat{b}_{\sigma, n_x, n_y}^\dagger(\omega) |vac\rangle = |\sigma\rangle \otimes |n_x, n_y\rangle \otimes |\omega\rangle$. Here we will focus on the spatial part of Eq. (29).

In order to introduce the link between the Wigner formalism used in previous sections and the single-photon description, let us consider the connection between the cross-spectral density $w_c(\mathbf{r}, \mathbf{r}')$ and the density matrix operator. The density matrix operator for a paraxial wave state $|\psi\rangle$ from Eq. (29) is $\hat{\rho} = |\psi\rangle\langle\psi|$. Here, we deal with coherent waves, but this formalism is more general, and can be extended to partially coherent waves. For coherent waves, the amplitude of the spatial distribution of the photon is defined by $\psi(\mathbf{r}) = \langle \mathbf{r} | \psi \rangle$. In contrast, partially coherent waves do not have a deterministic amplitude, but instead they are described by an ensemble of amplitudes with an associated probability, for example, consider the physical scenario of a phase that is stochastically varying. Within the density operator formalism, partially coherent waves can be described as $\hat{\rho} = \sum_k p_k \hat{\rho}_k = \sum_k p_k |\psi_k\rangle\langle\psi_k|$, where $\hat{\rho}_k$ is a coherent wave with an associated probability p_k . As it is expected for a probability distribution, $\sum_k p_k = 1$ must be satisfied. When $p_k = 1$ for a certain k we return to the coherent wave. Therefore, for both coherent and partially coherent waves, the cross-spectral density is defined as

$$w_c(\mathbf{r}, \mathbf{r}') = \langle \mathbf{r} | \hat{\rho} | \mathbf{r}' \rangle \quad (30)$$

where $\hat{\rho}$ is the density operator of the wave. In the particular case of coherent waves, the cross-spectral density reads as $w_c(\mathbf{r}, \mathbf{r}') = \psi(\mathbf{r})\psi^*(\mathbf{r}')$. As well as in the classical case (see Eq. (1)) the Wigner distribution related by the FT to the cross-spectral density is a faithful representation of quantum state.

Identically to previous sections in which light is considered to be a classical electromagnetic wave, we are interested in tomographic techniques to retrieve the WD and therefore the spatial structure of photons. The main difference between the quantum and the classical picture is the concept of measurement. When the square modulus of the amplitude of the photon is measured in a particular position, the quantum state collapses after the measurement and the information of the initial quantum state that we are interested in is lost. Due to this limitation, it is impossible to retrieve the quantum state of a single photon in a single shot. In general, all methods for characterizing quantum states of photons are based on an ensemble of photons, i.e., a set of many photons with the same quantum state. Then the strategy consists in measuring separately all photons and inferring the quantum state from the information obtained from these measurements.

A spatial structure of a photon propagating through a first-order optical system can be modified as explained in Eq. (12). Assuming that we have N identical photons, we send the photons one at the time through the optical system that performs the fractional FT and the image rotator. In each measurement, we measure a *click* in a particular transverse position of our detector. After repeating the experiment N times, we will obtain a distribution of *clicks* in our detector, related to the modulus square of the amplitude (at the position of the detector) of the quantum state. Using the same strategy than in the classical case, we implement the required transformations to retrieve the WD corresponding to a single photon by changing accordingly the optical system. Hence, the discussed PST techniques can be easily extended to the single-photon regime.

Note that the photon can also be described by a superposition of paraxial modes with different frequencies ω (Eq. (29)) and be localized in time. In that case, we can also apply the chronocyclic tomography strategies discussed for short pulses.

So far, the simple case of a single-photon state has been considered. However, there exist more complicated quantum states of light composed of different photons, and the number of photons not necessarily have to be well-defined (D'Ariano *et al.*, 2003).

Then the Eq. (29) given for single-photon state has to be modified in order to account for more than one photon. If there is well-defined number N of photons in the same mode, the quantum state corresponds to the Fock state given by

$$|\psi_F\rangle = \frac{[\hat{b}_{\sigma,n_x,n_y}^\dagger(\omega)]^N}{\sqrt{N!}} |\text{vac}\rangle \quad (31)$$

Other common states are the coherent and squeezed states that do not have a well-defined number of photons. For example, the coherent states can be described via the displacement operator as

$$|\psi_C\rangle = e^{\alpha \hat{b}_{\sigma,n_x,n_y}^\dagger(\omega) - \alpha^* \hat{b}_{\sigma,n_x,n_y}(\omega)} |\text{vac}\rangle \quad (32)$$

where α is related to the average photon number and might take a complex value. Note that by expanding the exponential a superposition of Fock states is obtained and then the photon number is not well-defined. In most applications of quantum tomography, there is some prior information about the system. For example, it might be the knowledge that the light is described by a coherent state and the problem is then reduced to the determination of the value of α .

Note that in the previous examples for the Fock and coherent states all photons are described by the same mode, which is the common situation in quantum optics experiments. However, there exist more complicated scenarios in which the quantum states of photons with different modes, including the spatial transverse structure, have to be retrieved. In this case the optical system used for quantum state characterization depends on the mode representation or encoding. For example, a mode representation could be a superposition of photons with different transverse spatial profile, or it could be a superposition of photons propagating in different directions, both being possible mode representations. In the latter, which is well-known in the context of linear optical quantum computing, the quantum state is represented by photons propagating in different directions in an optical circuit constituted by beam splitters, phase shifters, and mirror. In particular, it has been proven that any unitary transform in the Fock space for a specific mode can be implemented by using a set of beam splitters and phase shifters (Knill *et al.*, 2001). These transforms can be expressed by a similar mathematical formalism to the one introduced above for the PST characterization of the spatial structure of classical light.

The PST allows establishing a series of powerful techniques to retrieve both quantum and classical states of lights which are of relevance for a wide range of fields such as optical metrology, microscopy, astronomy, classical and quantum optics communication, to name a few.

Coordinate Transformations and the Hough Transform

Filippus S Roux, University of Witwatersrand, Johannesburg, South Africa and National Metrology Institute of South Africa, Pretoria, South Africa

Introduction

An optical coordinate transformation is a linear optical implementation of a class of point transforms that is applied to the intensity distribution of an optical beam. Such a coordinate transformation can be implemented with the aid of a thin optical element having a specially designed phase-only transmission function. The optical element is placed in the input plane where it modulates the input optical field in such a way that the subsequent linear optical system produces the required transformed optical field in the output plane. Another optical element with a phase-only transmission function is sometimes placed in the output plane to remove the residual phase, induced by the transformation, so that the transformed amplitude distribution would remain intact upon subsequent propagation (apart from normal diffraction).

The initial concept for the implementation of optical coordinate transformations was proposed in [Bryngdahl \(1974\)](#). However, for optical elements with continuous phase functions, this procedure can only implement geometrical transformations that obey a continuity condition ([Cederquist and Tai, 1984](#)). Subsequently, a number of techniques have been proposed to overcome this restriction. One way is to produce a multifaceted optical element with a discontinuous phase function ([Case et al., 1981](#)). Another approach is to separate the geometrical transformation into two cascaded geometrical transformations, each of which satisfies the continuity condition ([Stuff and Cederquist, 1990](#)). A third method ([Roux, 1994](#)) is to allow the phase function to contain phase singularities, which would produce optical vortices ([Nye and Berry, 1974](#)) in the propagating optical field.

Optical coordinate transformations have been used to implement, among others: a log-polar transform for rotation and scale invariant feature extraction ([Saito et al., 1983](#)); a rotationally symmetric beam-shaping system ([Han et al., 1983](#)); a ring-to-point transform ([Cederquist and Tai, 1984](#)); a rotation transformation ([Roux, 1993a](#)); and a polar formatting transform to compensate for distortion in synthetic-aperture radar data ([Roux, 1995](#)). Recently, a refractive optical implementation of the log-polar transform was proposed for the efficient measurement of the azimuthal index of Laguerre-Gauss modes ([Berkhout et al., 2010](#)).

A different kind of point transform is where the input and output coordinates are related by an implicit transformation equation. The Hough transform is an example of such an implicit transformation. It maps lines in the input plane to individual points in the output plane. After considering the optical implementation of coordinate transformation, we'll discuss the optical implementation of the Hough transform.

Coordinate Transformations

A coordinate transformation that can be implemented optically maps the points on a two-dimensional input plane $\mathbf{x}=(x,y)$ onto the points on a two-dimensional output plane $\mathbf{u}=(u,v)$. Being continuous and one-to-one, such a coordinate transformation is defined by a pair of equations, expressing the output coordinates in terms of functions of the input coordinates $u(\mathbf{x})$ and $v(\mathbf{x})$. These relationships are called the transformation equations, which can be represented as a vector field

$$\mathbf{u}(\mathbf{x}) = u(\mathbf{x})\hat{x} + v(\mathbf{x})\hat{y} \quad (1)$$

The optical implementation employs a phase-only transmission function to direct the light from each point in the input plane to the required location on the output plane. Such a phase-only transmission function can be physically realized as a thin refractive optical element or as a diffractive optical element. It can also be implemented with a programmable spatial light modulator.

Bryngdahl Method

First, we'll consider an optical system comprising a 2-f system with a phase-only transmission function located in the front focal plane, which serves as the input plane. Such a system is shown diagrammatically in [Fig. 1](#). The output amplitude distribution in the back focal plane (the output plane) of a 2-f system is given by the Fourier transform of the amplitude distribution in the input plane. For the case of the system in [Fig. 1](#), the amplitude distribution in the input plane is the input optical field times the phase-only transmission function. To implement the required geometrical transformation, the phase-only transmission function modulates the light at each point in the input plane with an appropriate spatial frequency so that the Fourier transforming action of the lens will place the light from that input point at the required location in the output plane.

Bryngdahl used the stationary-phase approximation to derive a set of differential equations that relates the transformation equations to the gradient of the phase of the transmission function in the input plane of the 2-f system. In vector notation, this

Fig. 1 Optical configuration of a 2-f system.

differential equation is given by

$$\nabla\theta(\mathbf{x}) = \frac{k}{f}\mathbf{u}(\mathbf{x}) \quad (2)$$

where $\theta(\mathbf{x})$ is the phase of the transmission function, k is the wave number and f is the focal length of the lens. Since we'll only work on the two-dimensional input and output planes, all vectors are assumed to be two-dimensional and the gradient operator only operates on the two-dimensional transverse plane $\nabla \equiv \hat{x}\partial_x + \hat{y}\partial_y$.

Note that, Eq. (2) only applies for the case of a 2-f system. One can also use an optical system without a lens, where the input and output planes are separated by a distance L that is large enough to allow the output to be given by Fresnel diffraction. In such a case, the differential equation is

$$\nabla\theta(\mathbf{x}) = \frac{k}{L}[\mathbf{u}(\mathbf{x}) - \mathbf{x}] \quad (3)$$

By solving the differential equation in either Eq. (2) or Eq. (3), depending on the system under consideration, one can obtain the required phase function for the transmission function in the input plane. The transmission function with this phase function can then be implemented with the aid of a refractive optical element or a diffractive optical element or simply a spatial light modulator to realize an optical system that would perform the required coordinate transform.

Continuity Condition

If the required phase function $\theta(\mathbf{x})$ in Eq. (2) is a continuous function, then $\nabla \times \nabla\theta = 0$. It would then imply that $\nabla \times \mathbf{u} = 0$ for both the 2-f system and the lens-less system. In other words, the transformation equations, expressed as a vector field, must be non-rotational. One can also express this requirement as a continuity equation, given by

$$\partial_y u(\mathbf{x}) = \partial_x v(\mathbf{x}) \quad (4)$$

By implication, the two transformation equations are not independent.

There are many useful transformations that do not obey the continuity condition in Eq. (4). A simple example is where the distribution is rotated by an angle α around the optical axis. The transformation equations for such a rotation transformation are

$$\begin{aligned} u(\mathbf{x}) &= \cos(\alpha)x - \sin(\alpha)y \\ v(\mathbf{x}) &= \sin(\alpha)x + \cos(\alpha)y \end{aligned} \quad (5)$$

Here, we have $\partial_y u(\mathbf{x}) = -\sin(\alpha)$, while $\partial_x v(\mathbf{x}) = \sin(\alpha)$. Since these transformation equations do not satisfy the continuity condition, the transformation cannot be implemented with an optical element having a continuous phase function.

There are a number of different approaches that one can follow to overcome the limitations imposed by the continuity condition in Eq. (4). We'll consider three such approaches: representing the transformation as two separate cascaded transformations, as discussed in Section Cascaded Transformations; implementing the transformation with a multifaceted transmission function, as discussed in Section Multifaceted Transmission Function; or incorporating phase singularities in the phase function of the transmission function, which is discussed in Section Transmission Function With Phase Singularities.

Cascaded Transformations

It was shown (Stuff and Cederquist, 1990) that coordinate transformations, which are bijective¹ geometrical transformations, can be implemented with either one or two transmission functions, depending on whether they obey the continuity condition or not. However, there does not seem to be a general approach to formulate the two separate geometrical transformations that would implement a geometrical transformation not satisfying the continuity condition.

A fairly simple example of such a cascaded implementation is where two mirror transformations are used to implement a rotation transformation. Unlike the rotation transformation, mirror transformations do obey the continuity condition. For a

¹A bijective transform is one-to-one and covers the whole domain.

Fig. 2 Two phase functions for the two cascaded mirror transformations, are shown in (a) and (b), respectively. Together they implement a 60 degree rotation. The phase is represented in terms of gray scales, with black and white representing zero and 2π , respectively.

mirror transformation with respect to an arbitrary angle α , the transformation equations are given by

$$u(\mathbf{x}) = \cos(\alpha)x + \sin(\alpha)y, v(\mathbf{x}) = \sin(\alpha)x - \cos(\alpha)y \quad (6)$$

Hence, $\partial_y u(\mathbf{x}) = \partial_x v(\mathbf{x}) = \sin(\alpha)$. If this mirror transformation is followed by another mirror transformation with $\alpha = 0$, the result is the rotation transformation, given in Eq. (5).

Using the differential equation for the 2-f system, given in Eq. (2), together with the mirror transformation equations in Eq. (6), we obtain a phase function given by

$$\theta(\mathbf{x}) = \frac{k}{2f} \cos(\alpha)(x^2 - y^2) + \frac{k}{f} \sin(\alpha)xy \quad (7)$$

This phase function defines the phase-only transmission function in the input plane of the first 2-f system. The output plane of the first 2-f system serves as the input plane for another 2-f system having a similar phase-only transmission function in its input plane, but with $\alpha = 0$. The output of the second 2-f system is the required transformed amplitude distribution, which in this case is a rotated version of the amplitude distribution in the input plane of the first 2-f system. Examples of the two phase functions for the two cascaded mirror transformations that together would implement a 60 degree rotation, are shown in Fig. 2.

Multifaceted Transmission Function

A general transformation can be implemented optically in a brute force approach, by discretizing the input and output planes. The input plane is divided into a grid of small areas. Each of these areas is then treated as a single point in the input plane, which is to be transformed to a single point in the output plane. A diffraction grating with the appropriate spatial frequency is then placed in each of the small areas. Each of these small areas acts like a small aperture that selects a part of the input field and modulates it with the particular diffraction grating function in that aperture. The effect is that the input field is divided into these input areas and each wavelet then gets diffracted in such a way that the light is placed at the correct location in the output plane.

The phase of the diffraction grating for a particular input area, labelled by the indices m and n for the x - and y -directions, respectively, is given by

$$\theta_{m,n}(\mathbf{x}) = \frac{k}{f} [u(x_m, y_n)x + v(x_m, y_n)y] \quad (8)$$

where (x_m, y_n) are the input coordinates at the center of the small input area and $u(x_m, y_n)$ and $v(x_m, y_n)$ denote the output coordinates that are associated with the input point at (x_m, y_n) . The transmission function for each area is then given by

$$t_{m,n}(\mathbf{x}) = \exp[i\theta_{m,n}(\mathbf{x})] \quad (9)$$

and the total transmission function $t_{\text{tot}}(\mathbf{x})$ is formed as the combination of the transmission functions of all the areas

$$t_{\text{tot}}(\mathbf{x}) = \sum_{m,n} t_{m,n}(\mathbf{x}) \prod \left(\frac{x}{\Delta x} - m, \frac{y}{\Delta y} - n \right) \quad (10)$$

where $\prod(\cdot)$ is a rectangular aperture function defining the regions of the small input areas.

Although this method can implement any coordinate transformation, the output field would have the appearance of a discrete array of spots, rather than a smooth optical field. By making the input regions smaller, the output spots would become bigger and be located closer to each other, so that they may eventually overlap. However, depending on the particular coordinate transformation that is being implemented, the spots may be closer to each other in one part of the output plane than in another. Moreover, the overlapping spots in the output plane may cause undesirable interference fringes.

Another result of the multifaceted transmission function is that the sharp boundaries between adjacent input regions cause additional diffraction effects that may be undesirable. One can reduce this effect by allowing the gratings in the different small regions to merge into those of adjacent regions by providing each with a smooth envelope function that extends into the adjacent region and merges with the envelope function of that region. In that case, one would replace the rectangular aperture function

Fig. 3 The phase function of a single isotropic phase singularity. In (a) the phase value is represented in terms of a gray scale, with black and white representing zero and 2π , respectively. Note that the discontinuity along the black-to-white transition is only an artifact of the representation, since 0 and 2π represents the same phase. In (b) a cyclic range of rainbow colors is used to represent the phase values, showing the fact that there is no discontinuity in the phase around the defect in the center.

$\Pi(\cdot)$, defined in Eq. (10), by a suitably smooth envelope function. The result would be a varying diffraction grating over the entire input plane. However, forked grating lines would appear at the boundaries where the grating periods don't match up exactly. These forked grating lines represent phase singularities in the phase of the transmission function, which is the topic of the next section.

Phase Singularities

To discuss the method based on the inclusion of phase singularities in the transmission function, we first need to consider phase singularities in general. Their role in those coordinate transformations that do not obey the continuity condition and the process to compute the required phase function are explained in Section Transmission Function With Phase Singularities.

Phase Functions

One can represent phase as a point on a unit circle around the origin on the complex plane. Each point on the circle represents a unique phase value and all possible phase values are represented by points on the circle. There is no 'largest value' or 'smallest value' for phase. A phase value of 2π represents the same phase as zero. The value of the phase always increases (decreases) for anticlockwise (clockwise) motion round the circle. The unit circle on the complex plane is an example of a compact domain, where the values remain finite even though one never reaches a boundary. This also implies that the circle has a nontrivial topological structure; it is not simply connected.

The topological properties of the configuration space of phase give phase functions special characteristics that make them different from ordinary functions.² A phase function $\theta(\mathbf{x})$ is a continuous mapping from the two-dimensional (x,y) -plane to the circle of phase values. The continuity of the mapping requires that a connected line of points on the (x,y) -plane maps to a connected line of points on the phase circle. The nontrivial topological structure of the circle now allows for the appearance of topological defects. Consider, for instance, all the possible ways that one can map a closed contour from the (x,y) -plane onto or into the circle of phase values. This could give connected phase values that are all located on one side of the circle, so that if the contour shrinks to a point on the (x,y) -plane, the phase values would also shrink to a point on the phase circle. However, if the mapping of the closed contour produces a wrapping around the phase circle, the phase values on one side of the phase circle would have to 'jump' to the other side when the closed contour shrinks to a point on the (x,y) -plane. The 'jumping' process represents a tearing of the topological space, which is not allowed for any process that conserves the topology of the space. This indicates the presence of a topological defect inside the closed contour on the (x,y) -plane.

For a phase function, such topological defects are called phase singularities, because at such a point the phase is undefined and around such a point the phase takes on all the possible phase values. It is therefore classified as an essential singularity. These phase singularities have topological charges, which may be positive or negative depending on the handedness of the wrapping. The topological charges can also be larger than 1 (or smaller than -1) depending on the number of times that the mapping wraps around the phase circle.

The phase function of a single isotropic phase singularity is shown in Fig. 3. Two different ways are used to represent the phase. Henceforth, phase functions are only presented in terms of gray scales.

Mathematically, the presence of a phase singularity inside a close contour can be determined with the aid of an index integral, which integrates the gradient of the phase along the closed contour. The result is an integer multiple of 2π :

$$\oint_C \nabla \theta(\mathbf{x}) \cdot d\hat{s} = 2\pi n \quad (11)$$

where n is an integer representing the net enclosed topological charge.

²In this context, an 'ordinary' function is one with a non-compact range that has no non-trivial homotopy groups.

As an example, consider a phase function that is given by the azimuthal angle $\phi(\mathbf{x})$, expressed as a function of Cartesian coordinates. In this case the index integral can be expressed as

$$\int_0^{2\pi} \partial_\phi \phi \, d\phi = 2\pi \quad (12)$$

As expected, one finds a phase singularity at the origin with a topological charge of $+1$. This result confirms that phase functions are not ordinary functions.

Derivatives of a Phase Function

Applying the Stokes theorem to Eq. (11), one finds

$$\int_A [\nabla \times \nabla \theta(\mathbf{x})] \cdot \hat{z} \, d^2x = 2\pi n \quad (13)$$

where A is the area enclosed by the contour. The expression in Eq. (13) implies that $\nabla \times \nabla \theta(\mathbf{x}) \neq 0$. In fact, the curl of the gradient of a phase function produces a Dirac delta function at the location of each phase singularity, multiplied by its topological charge (Roux, 2006)

$$[\nabla \times \nabla \theta(\mathbf{x})] \cdot \hat{z} = 2\pi \sum_p (\nu_p) \delta(\mathbf{x} - \mathbf{x}_p) \quad (14)$$

where ν_p represents the topological charge of each phase singularity and $\mathbf{x}_p$ is the location of the phase singularity. For example, in the case of a single phase singularity, as represented by a shifted function of the azimuthal angle, one gets

$$\nabla \times \nabla \phi(\mathbf{x} - \mathbf{x}_0) = 2\pi \delta(\mathbf{x} - \mathbf{x}_0) \hat{z} \quad (15)$$

Here the azimuthal angle represents the generic phase function for a single isotropic phase singularity, as shown in Fig. 3.

In more general terms, one can regard the right-hand side of Eq. (14) as a topological charge distribution $T(\mathbf{x})$. So then

$$\nabla \times \nabla \theta(\mathbf{x}) = 2\pi T(\mathbf{x}) \hat{z} \quad (16)$$

By integrating both sides of Eq. (16) over the area A , one recovers Eq. (13), with the understanding that the net topological charge is given by the integral of the topological charge distribution

$$n = \int_A T(\mathbf{x}) \, d^2x \quad (17)$$

General Phase Function

We see now that a phase function in general consists of a continuous part and a singular part. The continuous part is an ordinary function. The singular part can be represented as a sum of shifted versions of the azimuthal angle, multiplied by their topological charges. Hence, a general phase function can be expressed by

$$\theta(\mathbf{x}) = \theta_{\text{cont}}(\mathbf{x}) + \sum_p (\nu_p) \phi(\mathbf{x} - \mathbf{x}_p) \quad (18)$$

where the first term on the right-hand side represents the continuous part and the second term represents the singular part.

Transmission Function With Phase Singularities

Required Topological Charge Distribution

With the new understanding of phase functions, we can take another look at the continuity condition. First we note that the requirement for a continuous phase function is the reason why this restriction exists, because it implies that $\nabla \times \nabla \theta_{\text{cont}}(\mathbf{x}) = 0$. Therefore, if we have a set of transformation equations for which $\nabla \times \mathbf{u} \neq 0$, then it simply means that we need to include phase singularities in the phase function.

Let's apply once again the curl on both sides of Eq. (2), this time using Eq. (16). Then we find that

$$\nabla \times \nabla \theta(\mathbf{x}) = 2\pi T(\mathbf{x}) \hat{z} = \frac{k}{f} \nabla \times \mathbf{u}(\mathbf{x}) \quad (19)$$

The rotational part of the vector field $\mathbf{u}(\mathbf{x})$ precisely gives the topological charge distribution that is required to implement the transform

$$T(\mathbf{x}) = \frac{1}{\lambda f} [\nabla \times \mathbf{u}(\mathbf{x})] \cdot \hat{z} \quad (20)$$

Note, however, that the topological charge distribution thus obtained is a continuous function and not a summation of discrete topological charges associated with distinct phase singularities. Since phase singularities are by their very nature always discrete

points, the required topological charge distribution can at best be approximated by an arrangement of phase singularities over the (x,y) -plane.

The example of the rotation transformation, defined in Eq. (5), requires a constant topological charge distribution given by

$$T(\mathbf{x}) = \frac{1}{\lambda f} [\partial_x v(\mathbf{x}) - \partial_y u(\mathbf{x})] = \frac{2\sin(\alpha)}{\lambda f} \quad (21)$$

It should be noted that such a constant topological charge density cannot be implemented over an arbitrary large region. Due to limitations on the density of phase singularities (Roux, 2003), the maximum radius over which one can maintain a constant topological charge density, as given in Eq. (21), is

$$R_{\max} = \frac{f}{\sin(\alpha)} \quad (22)$$

For larger rotation angles α , one would need to increase the focal length.

Continuous Part of the Phase Function

While the required topological charge distribution is readily computed with the aid of Eq. (20), the continuous part of the phase function requires more attention. One needs to obtain a set of modified transformation equations that excludes the contribution of the phase singularities. Such a modified set of transformation equations would then obey the continuity condition (representing a non-rotational vector field) that could be used to compute a continuous phase function.

The total phase function, given in Eq. (18), consist of a continuous part and the singular part. Computing the gradient of the total phase function, one obtains

$$\nabla\theta(\mathbf{x}) = \nabla\theta_{\text{cont}}(\mathbf{x}) + \sum_p (v)_p \nabla\phi(\mathbf{x} - \mathbf{x}_p) \quad (23)$$

The left-hand side is given by the transformation equations according to Eq. (2). The required transformation equations for the continuous part of the phase function is thus given by

$$\nabla\theta_{\text{cont}}(\mathbf{x}) = \frac{k}{f} \mathbf{u}(\mathbf{x}) - \sum_p (v)_p \nabla\phi(\mathbf{x} - \mathbf{x}_p) \quad (24)$$

It now remains to determine the last term (the singular term) on the right-hand side of Eq. (24). One can reconstruct the singular term from the topological charge distribution that is required to implement the transform. Although we don't know the locations and topological charges of the individual phase singularities, as required in the last term of Eq. (24), we do know the required topological charge distribution. So one can convert the summation into an integral, where we replace the individual topological charges with the known topological charge distribution

$$\sum_p (v)_p \nabla\phi(\mathbf{x} - \mathbf{x}_p) \rightarrow \int T(\mathbf{x}') \nabla\phi(\mathbf{x} - \mathbf{x}') d^2x' \quad (25)$$

The result is a convolution integral, which convolves the topological charge distribution with the gradient of a single phase singularity function. The resulting differential equation for the continuous part of the phase function now reads

$$\nabla\theta_{\text{cont}}(\mathbf{x}) = \frac{k}{f} \mathbf{u}(\mathbf{x}) - 2\pi \mathbf{F}_s \quad (26)$$

where

$$2\pi \mathbf{F}_s = \int T(\mathbf{x}') \nabla\phi(\mathbf{x} - \mathbf{x}') d^2x' \quad (27)$$

is the singular phase gradient.

As a test of consistency, we apply a curl operation on both sides of Eq. (26). The result gives

$$\nabla \times \nabla\theta_{\text{cont}}(\mathbf{x}) = \frac{k}{f} \nabla \times \mathbf{u}(\mathbf{x}) - 2\pi \nabla \times \mathbf{F}_s \quad (28)$$

where

$$2\pi \nabla \times \mathbf{F}_s = \int T(\mathbf{x}') \nabla \times \nabla\phi(\mathbf{x} - \mathbf{x}') d^2x' \quad (29)$$

Since $\theta_{\text{cont}}(\mathbf{x})$ is an ordinary function, the left-hand size of Eq. (28) becomes zero. One can use Eq. (15) to evaluate the integral in Eq. (29). In the end, Eq. (28) becomes

$$0 = \frac{k}{f} \nabla \times \mathbf{u}(\mathbf{x}) - 2\pi T(\mathbf{x}) \quad (30)$$

which is in agreement with Eq. (19). Hence, we have confidence that Eq. (26) represents the required differential equation for the continuous part of the required phase function.

Gradient of the Singular Phase Function

The evaluation of the convolution integral in Eq. (27) requires the expression for the gradient of the generic function for a single phase singularity. One can express the azimuthal angle in terms of the transverse Cartesian coordinate by³

$$\phi(\mathbf{x}) = \frac{1}{i2} \ln \left(\frac{x + iy}{x - iy} \right) \quad (31)$$

The gradient of this phase function is

$$\nabla \phi(\mathbf{x}) = \frac{x\hat{y} - y\hat{x}}{x^2 + y^2} = \frac{\hat{z} \times \mathbf{x}}{|\mathbf{x}|^2} \quad (32)$$

The convolution integral in Eq. (27) thus becomes

$$2\pi F_s = \int T(\mathbf{x}') \frac{\hat{z} \times (\mathbf{x} - \mathbf{x}')}{|\mathbf{x} - \mathbf{x}'|^2} d^2 x' \quad (33)$$

or, by redefining the integration variable,

$$2\pi F_s = \int T(\mathbf{x} - \mathbf{x}') \frac{\hat{z} \times \mathbf{x}'}{|\mathbf{x}'|^2} d^2 x' \quad (34)$$

The expressions in Eqs. (33) and (34) are real-valued. One can simplify the expressions by combining the x - and y -components as the real and imaginary parts of the expression. The results are

$$2\pi F_s = \int \frac{iT(\mathbf{x} - \mathbf{x}')}{x' - iy'} d^2 x' \quad (35)$$

or

$$2\pi F_s = \int \frac{iT(\mathbf{x})}{(x - x') - i(y - y')} d^2 x' \quad (36)$$

whichever is more convenient to use. The real part of the resulting integral is the x -component and the imaginary part is the y -component.

Application: Rotation Transform

For a constant topological charge density, such as the one required for the rotation transformation, the integral for the singular part of the phase gradient can be readily evaluated with the aid of contour integration. For this purpose we use the expression in Eq. (36) and obtain the result

$$2\pi F_s = \int \frac{iT_0}{(x - x') - i(y - y')} d^2 x' = i\pi(x + iy)T_0 \quad (37)$$

where T_0 represents a constant topological charge density.

For the rotation transformation, the singular part of the phase gradient is therefore given by

$$2\pi F_s = \frac{k}{f} (ix - y) \sin(\alpha) \quad (38)$$

which means that

$$2\pi F_s = \frac{k}{f} (x\hat{y} - y\hat{x}) \sin(\alpha) \quad (39)$$

The differential equation for the continuous phase function is obtain by substituting the transformation equations and the singular phase gradient into Eq. (26). For the rotation transformation, the differential equation becomes

$$\nabla \theta_{\text{cont}}(\mathbf{x}) = \frac{k}{f} \cos(\alpha) \mathbf{x} \quad (40)$$

This differential equation can now be solved to give

$$\theta_{\text{cont}}(\mathbf{x}) = \frac{k \cos(\alpha)}{2f} (x^2 + y^2) \quad (41)$$

The continuous phase function is a lens function with a focal length that depends on the rotation angle. Together with the required topological charge distribution given in Eq. (21), one can now construct the complete phase function that is required to implement the rotation transformation, using a 2-f system. A part of the phase function is shown in Fig. 4. It contains the phase singularities placed on an equilateral triangular grid.

³This definition in terms of the $\ln$ -function is preferred over that with the $\arctan$ -function, because the latter only produces phase values between $-\pi/2$ and $\pi/2$.

Fig. 4 Part of the phase function with phase singularities of the transmission function for a 45 degree rotation.

Hough Transform

Implicit Transformation

The coordinate transformations, which are discussed above, are defined in terms of a pair of explicit equations that give the output coordinates in terms of the input coordinates and are therefore called explicit transformations. Such transformations are one-to-one, meaning that each output point is associated with only one unique input point.

There are also other transformations that produce one-to-many mappings between input and output points; one input point goes to a set of different output points. Such transformations are defined in terms of implicit equations – a single expression that contains the input coordinates and the output coordinates implicitly – and are therefore referred to as implicit transformations.

Definition of the Hough Transform

An example of an implicit transformation is the conventional Hough transform (Duda and Hart, 1972), which maps lines in the input plane to points in the output plane. The implicit equation for the Hough transform is given by

$$u = x \cos(Kv) + y \sin(Kv) \quad (42)$$

where K is a constant parameter that converts the output coordinate v into an angle. One can define $K = 2\pi/L$, where L is the width of the output region in the v -direction.

For a fixed output point (u, v) , the equation in Eq. (42) describes a line in the input plane. Alternatively, for a fixed input point (x, y) the equation in Eq. (42) describes a sinusoidal curve in the output plane.

Optical Implementation

The optical implementation of the Hough transform can be done with the aid of a single transmission function (Roux, 1993b). Such a transmission function needs to be constructed as a superposition of several transmission functions, each implementing an explicit transformations. Here, we'll describe the implementation with the aid of a multifaceted transmission function, as discussed in Section Multifaceted Transmission Function.

The transmission function of a general optical transform (explicit or implicit), implemented with a multifaceted transmission function, can be expressed as

$$t(\mathbf{x}) = \sum_{m,n,p,q} \alpha_{mnpq} A(x - m\Delta x, y - n\Delta y) \times \Phi^*(p\Delta u, q\Delta v; x, y) \quad (43)$$

where α_{mnpq} denotes the binary coefficients (either equal to 1 or 0) that indicate whether or not there is a link between particular input and output points; $A(\mathbf{x})$ is a suitable envelope function; and $\Phi^*(\mathbf{u}; \mathbf{x})$ is the complex conjugate of the appropriate kernel function (Fourier or Fresnel), depending on the type of optical system in which the transform is implemented. The grid spacings in the input and output planes along the two orthogonal directions are denoted by Δx , Δy , Δu and Δv , respectively. The envelope function could be $\prod(\cdot)$, which is used in Eq. (10), or it could be a smoothing window function to produce a more continuous transmission function.

Fig. 5 The phase function of the transmission function for the Hough transform.

Fig. 6 Output diffraction pattern produced by a fully illuminated transmission function for the Hough transform.

The phase function of the transmission function for an optically implemented Hough transform is shown in [Fig. 5](#). It was computed with [Eq. \(43\)](#) for an implementation in a 2-f system. The Hanning window function was used as envelope function. Using the resulting transmission function, we calculated the diffraction pattern in the output plane when the transmission function is fully illuminated. It is shown in [Fig. 6](#). The diffraction pattern contains an array of discrete output points as produced due to the discrete nature of the implementation. Each output point is elongated in a direction perpendicular to the orientation of the line in the input plane that is mapped to that output point.

General Comments

There are a number of general considerations that one needs to keep in mind when designing optical systems to implement coordinate transformations or more general implicit transformations, such as the Hough transform. These are:

- The stationary phase approximation that is used to derive the differential equations for the phase of the transmission function ignores the amplitude distribution of the incident optical field. As a result, the effect of the phase of the incident optical field is not taken into account in the design of the optical element. If the incident optical field contains a severely tilted phase front at the location of a particular input point, the location of the associated output point would be noticeably shifted away from the

location defined by the transformation. For instance, a helical phase that is unwrapped by the log-polar transform would give a distorted output line in the case of high azimuthal index in the incident optical field.

- The size of an input area, restricted by an aperture, gives rise to a finite area in the output plane with a minimum size. For a smaller (larger) input area, the size of the output area becomes larger (smaller). This relationship is well-known for the 2-f system, where the input and output distributions are related by a Fourier transform,

$$d_{\text{out}} = \frac{\lambda f}{d_{\text{in}}} \quad (44)$$

where d_{in} and d_{out} represent the sizes of the input and output areas, respectively. A similar relationship applies for other systems such as the lens-less system.

The relationship between the sizes of these areas in the input and output can be used to compute a quantity called the space-bandwidth-product (SBP), which is determined as follows. The size of the total usable output area defines a smallest feature size in the input plane via the Fourier relationship in Eq. (44). Anything smaller would scatter light beyond the boundary of the usable output area. At the same time, the input plane also have a finite size for its total usable area that produces a small spot in the output, which thus defines the resolution in the output plane. The SBP is now given by the ratio of the total input area divided by the smallest feature size and it is also equal to the ratio of the total output area divided by the smallest resolution cell in the output plane.

A coordinate transformation, defines a mapping from separate points on the input plane to distinguishable points on the output plane. In practice, these points would be represented by finite size areas both on the input and the output planes. What do the sizes of these areas need to be and how many can there be? One cannot use the number given by the SBP of the system as an indication of the number of points that are mapped between input and output, because if we use the smallest input feature size in the input, then the output points would be as large as the entire output area. Moreover, if one wants the output points to be the size of the resolution cells, the input points would need to cover the entire input area. Hence, the optimal number of points that can be used (in the case of the rotation transform, for instance) would be the square root of the SBP. This gives as many distinguishable output points as separated input points. For this reason, a coordinate transform is not an effective way to implement beam shaping.

- Depending on the type of implementation method that is used, one may have to accept a limited diffraction efficiency. The result is that there could be undiffracted light that also propagates together with the diffracted light, after passing through the device that implements the transmission function. To separate the diffracted light from the undiffracted light, one can add an overall phase grating (linear phase tilt) to the phase of the transmission function. The magnitude of the phase tilt needs to be larger than the largest spatial frequency in the original phase function to ensure that the desired first diffraction order would be completely separated from the undiffracted zeroth order. The desired first diffraction order then appears next to the undiffracted zeroth order in the output plane and can be separated from it by spatial filtering.
- In the case of an implicit transformation where one input point is mapped to several output points, such as with the Hough transform, the transmission function consists of the superposition of several transmission functions for the individual output points. The superposition causes interference, which modulates the amplitude (magnitude) of the resulting transmission function. As a result the final transmission function for the total implicit transform is not a pure phase function (it is not 'phase-only'), such as the transmission functions for the individual output points.

This gives rise to a number of consequences. To implement the complex amplitude of the total transmission function in a phase-only device, such as a spatial light modulator or diffractive optical elements, special encoding techniques need to be used. Alternatively, one can use older technologies that incorporate absorption. The modulated amplitude of the total transmission function implies that some of the incident optical power would be lost due to absorption or scattering, depending on how the complex amplitude of the transmission function is implemented. The result is a poor power efficiency for the implementation. One can try to use only the phase of the total transmission function to implement a phase-only optical transform, but in general the resulting transformation would then suffer from low fidelity.

Conclusions

Point transforms that are implemented in linear optical systems can be divided into explicit transformations, such as coordinate transformations, and implicit transformations, such as the Hough transform. Explicit transformations include those that only require a continuous phase function in the transmission function and therefore satisfy the continuity condition and those that also require phase singularities in the phase function of the transmission function and therefore do not satisfy the continuity condition.

Those explicit transformations that do satisfy the continuity condition can be implemented by a direct solution of the Bryngdahl differential equations. Explicit transformations that do not satisfy the continuity condition require additional attention. These explicit transformations either need to be separated into two cascaded explicit transformations, each satisfying the continuity condition or they need to be implemented as a multifaceted transmission function or they need the inclusion of phase singularities in the phase function of the transmission function.

The Hough transform is an implicit transformation that maps lines in the input plane to separate points in the output plane. It can be implemented as a superposition of several discrete transmission functions that map particular input points to particular output points.

The optical implementation of geometrical transformations provide a fast effective way to process optical information. However, care must be taken in the design of these systems to ensure that the implementation provide an accurate result.

Introduction

Sometimes great revolutions occur in science. All the different branches of physics had short periods of time where new ideas flooded their communities and sparked new technologies. Perhaps, Optics has been the most affected by those kinds of revolutions. We can clearly see at least three periods of time that were crucial to the development of light sciences as we know them today: the improvement in optical lenses fabrication, the generation of laser based light sources, and the development of electronic light sensors. The first one occurred in the 19th century, thanks to the works of Zeiss, Schott, and Abbe. They provided not only technical developments in the fabrication of lenses, but also the theoretical framework of modern optics. In the 1950s, the first laser sources appeared, and proved to be exceptional light sources that rapidly replaced white light sources in almost every experiment. With their use, novel techniques emerged, such as lithography, range measuring, and laser cutting. Furthermore, new devices were developed around them, such as optical disk drives. Lastly, at the end of the 1960s, charge-coupled devices (CCD) were invented. Now, optical fields could be digitally stored, and soon digital imaging techniques provided information that would have never been possible by working with conventional photographic films.

Even though this last revolution happened half a century ago, it slowly started a trend that continues today: the symbiosis of Electronics, Computer Science and Optics. Now, new optical techniques not only need to build optical systems considering lenses and light sources, but also the electronics present in their detectors and the computer algorithms they use to recover useful information. Moreover, new electronical devices have been built to control light, such as spatial light modulators, optical filters, etc. This blending of disciplines has proved to be an exceptional tool in a plethora of industries, life sciences, telecommunications, and astronomy.

Although CCD and complementary metal-oxide-semiconductor (CMOS) sensors have established as the way-to-go technology in digital imaging, several limitations remain unsolved. Obtaining images in low light level scenarios, in exotic ranges of the electromagnetic spectrum and at extremely high speeds still entails very expensive devices or with great limitations regarding spatial resolution and response time. Due to this, scientists have never stopped their search for new imaging modalities using different detectors. One of the modern solutions to these problems consists of using very specialized sensors without spatial resolution. One can think of those detectors as a digital camera with only one pixel (thus they are usually called single-pixel detectors) (Duarte *et al.*, 2008). Several questions should arise now: why using just one pixel? and, how do I obtain an image (with hundreds or thousands of pixels) with just a single-pixel detector?

The first question has a simple explanation. Building just one sensor with fast response time, sensibility or spectral response is usually easy, and it is always easier than building an array of thousands or millions of sensors with the same characteristics. Then, these cameras using single-pixel detectors present enhanced capabilities in challenging scenarios for traditional digital cameras. Now, the second question needs a little longer explanation, which we will see in the following section.

Single-Pixel Imaging Basics

In order to understand the operation of a single-pixel camera, we can start with a conventional digital camera, as shown in Fig. 1. In a conventional setup, the scene to be acquired is imaged with the aid of an optical system (think of the photographic objective of a digital camera, for example) onto the sensor. Due to image formation laws, each region of the scene is imaged onto a different

Fig. 1 Conventional digital camera setup. Left: using an imaging system, different regions of the scene are imaged onto different regions of the sensor, that measures the light irradiance. Using this information, a digital image is acquired. Right: as an array detector is used, this process is made in parallel, and each pixel of the detector obtains the information of a different region of the scene at the same time.

region of the sensor, so we have a 1:1 map between regions of the scene and regions of the sensor. Now, each pixel of the sensor measures the light irradiance coming from the scene. In a conventional CCD sensor, every pixel measures at the same time, so the image is acquired in a single shot. However, there are other ways of obtaining the same information.

One can illuminate only a small region of the scene (either by using a galvanometric mirror and a laser beam, or with a spatial light modulator), and measure the light irradiance coming from that region with a detector. This detector does not need to have millions of pixels any more, as light is collected with the optics onto a small spot, and the only relevant quantity to measure is not where the light goes to, but the amount of light coming from the scene. This is usually known in the imaging community as raster scanning, and it's the common operation mode for techniques such as confocal microscopy. The process is depicted in Fig. 2. Now, as the detector does not need spatial resolution, instead of a CCD sensor, different sensors can be used. For example, if one needs to work in low light level scenarios, photomultiplier tubes or photon counting detectors can be used. Even beam spectrometers and polarimeters have been used, providing polarimetric and multispectral images. This measurement process can be depicted by using simple mathematical operations. We consider a bidimensional object, $O(x, y)$. In order to obtain an image, we make the superposition of the object and a function that belongs to an orthogonal basis. In the raster scanning example, those functions are Dirac deltas, each one centered at a different spatial position. Then, each measurement, I_p , can be expressed as

$$I_p = O(x, y) \cdot \delta_p(x - x_p, y - y_p) \quad (1)$$

For each delta function, the single-pixel detector measures the amount of light coming from the object. After all the measurements are done, we can recover the object with the equation

$$O = \sum_p I_p \cdot \delta_p \quad (2)$$

It must be stated that, in order to recover an image with a number N of pixels, N delta functions need to be generated and sequentially measured with the detector, whereas in a conventional camera all the measurements are done in one single shot.

After the introduction of the raster scanning approach, it is easy to understand that there is no need to limit oneself to the use of delta functions. The same mathematical problem can be solved in any base of orthogonal functions, and this knowledge can be very useful in practical scenarios. As shown in Fig. 3, now instead of scanning the scene, different light patterns (functions of the basis) are sequentially generated onto the object, performing what is usually known as a basis scan. The main advantage of using different functions is that, instead of just illuminating a small region of the scene, several parts of the object are lighted at the same time. This increases the signal level at the detector, which ultimately improves the signal-to-noise ratio of the measurements. This is usually known as the Fellgett or multiplex advantage. Here, a plethora of functions have been discussed in the references, such as Fourier functions, DCT, and wavelets. Even non-orthogonal functions, such as random functions, can be used to obtain images, as

Fig. 2 Raster scanning imaging. The scene under study is scanned with a light beam, and the reflected irradiance is collected by an optical system and measured with a single-pixel detector. By scanning the full scene, the image can be recovered.

Fig. 3 Basis scanning imaging. The scene under study is lighted with a complete set of functions from an orthogonal basis, and the reflected irradiance is collected by an optical system and measured with a single-pixel detector. After all the functions have been projected, the set of measurements can be used to recover the image of the scene.

in the case of computational ghost imaging techniques. Each one of the basis presents its benefits and characteristic experimental implementations given its mathematical properties, and usually the choice between one on another can be made depending on the specifications of the device that one wants to build. Here, we are going to discuss the use of Walsh-Hadamard functions, its properties, and the requirements needed in order to build a single-pixel camera using them.

Walsh-Hadamard Single-Pixel Imaging

Walsh functions can be derived from Hadamard matrices, which are square matrices with dimensions of power of 2, entries either $+1$ or -1 , and the property that the product of two different rows or columns is zero (Pratt *et al.*, 1969) (see Fig. 4). Then, each row (column) can be understood as a square binary function which is orthogonal to all the other rows (columns). Hadamard matrices can be calculated for arbitrary big dimensions, and are easily stored and transmitted. Furthermore, due to being binary matrices, its technical implementation using spatial light modulators tends to be straightforward. Given those reasons, they are an excellent candidate to operate in a single-pixel architecture. Using vector form, now the measurement process can be described by

$$y = H \cdot x \quad (3)$$

where the object under study is denoted by a vector, x , containing the N pixels of the scene arranged in column form. The measurement process is represented by a Hadamard matrix, H , with dimension $N \times N$. Each row of this matrix contains a Walsh function. The measurements are arranged in the column vector y . In each element of the measurement vector the superposition of a Walsh function and the whole object is stored. This process of projecting the Walsh functions and measuring the resulting irradiance can be understood as an optical way of calculating the Walsh-Hadamard transform of the object (see Fig. 5). This is similar to the measurement of the Fourier Transform of an object by using a digital camera in the focal plane of a lens. Finally, after the measurements are done, one can recover the object by inverting the problem in Eq. (3). This can also be understood as performing the inverse Walsh-Hadamard transform of the measurement vector, y .

However, there can be a problem regarding the implementation of Walsh functions in spatial light modulators. As their entries consist of either $+1$ or -1 , amplitude modulators cannot directly implement Walsh functions (there is no available -1 state). A usual workaround entails the use of two different functions to codify a function. Instead of working with the true functions, a Hadamard matrix can be expressed as $H = H^+ - H^-$. The first matrix is built by substituting the -1 entries by 0, and the second one by replacing the $+1$ entries by zero, and the -1 entries by 1. Then, the measurement process can be expressed by

$$y = H \cdot x = H^+ \cdot x - H^- \cdot x \quad (4)$$

which matrices can be easily codified on amplitude spatial light modulators. It has to be noted that, if one uses phase spatial light modulators, this problem does not occur. However, due to the extremely fast operation modes of amplitude spatial light modulators and the sequential nature of single-pixel cameras, those are the ones usually used.

Once the fundamentals of Walsh-Hadamard imaging have been established, here we show an example of a single-pixel camera using a digital micromirror device (DMD) as an amplitude spatial light modulator. A scheme of the camera setup is shown in Fig. 6. Single-pixel imaging can be divided into two main stages: illumination (or codification) and detection. In the illumination

Fig. 4 Hadamard matrix and patterns example. Left: Hadamard matrix of dimension 64. White regions represent $+1$ entries and black regions represent -1 entries. Right: Hadamard patterns derived from the Hadamard matrix. In order to build each one of the 64 patterns, one row of the matrix is selected and arranged into a 8×8 pattern. Two example patterns, highlighted red and blue, are marked with their correspondent rows of the Hadamard matrix.

Fig. 5 Single-pixel Hadamard measuring fundamentals. The object is measured by making the projections onto the basis of Hadamard patterns. Those projections consist on overlapping both the object and each Hadamard pattern, and then measuring the total irradiance coming to the detector. By doing this, one gets the decomposition of the object in the Hadamard basis (this graph is the 1D Walsh-Hadamard transform of the object expressed in vector form). Once this decomposition is measured, the recovery can be obtained by performing the inverse Walsh-Hadamard transform of the coefficient vector.

Fig. 6 Single-pixel camera setup. Light coming from a light source (LS) is structured with a spatial light modulator (SLM). An image of the SLM is projected onto the object (OBJ) with several lenses and a beam-splitter (BS). After the superposition of both the Walsh-Hadamard functions and the object, the resulting irradiance is measured with a single-pixel detector (a photodiode in this case, PD).

stage, a light source illuminates a spatial light modulator, where the Walsh functions are generated. In this case, each one of the rows of the Hadamard matrix is rearranged in a bidimensional mask, usually called Hadamard pattern. Those patterns are projected into the scene that one wants to measure with the aid of an optical projection system. Then, the object and the Hadamard patterns overlap in one plane. In the detection stage, the resulting light distribution is collected with the aid of another optical system. A single-pixel detector measures this irradiance value, which is the projection of the object into one of the functions of the Walsh basis. Then, the spatial light modulator codifies another Walsh function and the detector measures again. After the full set of Hadamard patterns have been projected, the image of the object can be recovered. Two examples of images obtained by using this approach are shown in Fig. 7.

It must be stated that the spatial codification of information is realized when both the Hadamard patterns and the object overlap. Here we have shown one way of doing this, by projecting the patterns generated by the spatial light modulator onto the object. However, this projection can be done in different ways. For example, one can image the object onto the spatial light modulator with an optical system, and then make the overlapping in the spatial light modulator plane. After that, light is collected and measured with a single-pixel detector in the same way as in the first approach. This flexibility can be exploited in different scenarios, given that sometimes it is easy to work with an active illumination (sending light patterns to an object) and sometimes it is better to work in a passive configuration (imaging the scene onto the spatial light modulator).

Walsh-Hadamard Single-Pixel Applications

Given the benefits mentioned before, examples of single-pixel imaging techniques using Walsh-Hadamard functions can be extensively found in the references. They can be divided in four main groups. First, given the ease to build single-pixel detectors

Fig. 7 Single-pixel imaging using Hadamard patterns. In the top row, we show a 256×256 pixels LEGO® Ned Flanders picture (left) and its single-pixel reconstruction. In the bottom row, we show a 512×512 pixels USAF1951 test image (left) and its single-pixel reconstruction (right). Images extracted from Soldevila, F., Salvador-Balaguer, E., Clemente, P., Tajahuerce, E., Lancis, J., 2015. High-resolution adaptive imaging with a single photodiode. *Scientific Reports* (Nature Publishing Group) 5, 7 (Article No. 14300). Licensed under CC BY 4.0.

that work in exotic ranges of the spectral domain, multiple single-pixel cameras have been built in the IR and THz spectral regions (Radwell *et al.*, 2014; Watts *et al.*, 2014). Second, using simple detectors in combination with other optical and mechanical elements has allowed to perform multidimensional imaging. Here we can name multi and hyper spectral imaging (Soldevila *et al.*, 2013; Li *et al.*, 2017; Studer *et al.*, 2012), polarimetric imaging (Durán *et al.*, 2012; Welsh *et al.*, 2015), phase imaging (Clemente *et al.*, 2013), and 3D imaging (Zhang *et al.*, 2016), among others. Third, given the simplicity of the detection scheme, dedicated sensors can also be used to work in challenging scenarios, such as low-light level regimes, by using photomultiplier tubes or photon counting detectors. This has enabled single-pixel cameras to provide images, for example, in presence of highly scattering media, where distinguishing between non-scattered photons and diffuse light is of paramount interest (Tajahuerce *et al.*, 2014; Durán *et al.*, 2015). Lastly, single-pixel ideas have also been applied to well established optical techniques, improving their performance in demanding situations. Here we can name several applications, such as improving the SNR in two-photon microscopy (Ducros *et al.*, 2013) and photoacoustic imaging (Wang *et al.*, 2012), and enhancing resolution in traditional microscopy setups (Rodríguez *et al.*, 2014).

Challenges, Future Work

The main drawback of single-pixel cameras is the need to perform a sequential codification of information: whereas a traditional digital camera images the scene in a single shot, single-pixel cameras need to project a set of patterns onto the scene to recover an image. Furthermore, the higher the spatial resolution one wants to obtain, the higher the number of projections that need to be measured. Even though fast spatial light modulators are used, such as digital micromirror devices, that have repetition rates above 20 kHz, images higher than 64×64 pixels are rarely seen in applications where real-time operation is needed. For several applications, this resolution is high enough, but there are situations where high spatial resolution is needed, such as medical imaging.

In order to tackle this problem, multiple approaches have been proposed. Using Compressive Sensing techniques enable single-pixel cameras to reduce the number of required pattern projections (Duarte *et al.*, 2008; Candès, 2006; Romberg, 2008). Even though they usually entail high post-processing times, novel approaches have also been used to provide real-time video (Sankaranarayanan *et al.*, 2012). Other techniques, based on adaptive algorithms, have also been proposed as a way to reduce the measurement time with no need of complex post-processing stages (Soldevila *et al.*, 2015; Phillips *et al.*, 2017). However, none of those solutions have been able to provide results comparable to traditional digital cameras in terms of spatial resolution and frame

rate as of today. Further development in both computational algorithms and technical improvements in the fabrication of spatial light modulators (i.e., the development of faster SLMs) will be key to solve the present limitations of single-pixel cameras.

Linear Canonical Transforms

Kurt B Wolf, National Autonomous University of Mexico, Cuernavaca, Morelos, Mexico

© 2018 Elsevier Ltd. All rights reserved.

Introduction

Canonical transformations preserve the *structure* of Hamiltonian systems, be they *classical* as geometric optics or classical mechanics, or *wave* as monochromatic optics or quantum mechanics. When these transformations are *linear*, they can be represented by matrices, a most useful technique to keep account of their composition, which facilitates finding the end product of optical elements in a setup.

One can broadly define a D -dimensional system to be *Hamiltonian* when it contains variables or observables of *position*, $\mathbf{Q} = \{Q_i\}_{i=1}^D$, and an equal number of *momentum* variables or observables $\mathbf{P} = \{P_i\}_{i=1}^D$, which constitute its *phase space*; and a Hamiltonian function $H(\mathbf{Q}, \mathbf{P})$ that determines its *canonical evolution* along an optical axis z , or time t as in mechanics. If the transformation is to be *linear*, one must assume that phase space is the full real $2D$ -dimensional space $\mathbb{R}^{2D}$. This proviso allows only *paraxial* optical models to be addressed directly, as well as non-relativistic classical and quantum mechanics, since their treatment is mathematically similar to the corresponding classical and wave models in paraxial optics.

Conservation of Hamiltonian Structure

An important property of Hamiltonian systems is their *structure*; this boils down to a set of relations that must be conserved between the phase space coordinates under any transformation: *Poisson brackets* in the classical models and *commutators* in the wave models, namely

$$\{q_i, p_j\} = \delta_{ij}, \quad \{q_i, q_j\} = 0, \quad \{p_i, p_j\} = 0, \quad q_i \equiv Q_i \in \mathbb{R} \quad (1)$$

$$[\hat{Q}_i, \hat{P}_j] = i\hbar \delta_{ij}, \quad [\hat{Q}_i, \hat{Q}_j] = 0, \quad [\hat{P}_i, \hat{P}_j] = 0, \quad \hat{Q}_i \equiv Q_i \text{ on } \mathcal{L}^2(\mathbb{R}^D) \quad (2)$$

These operations are bilinear: $\{[c_1 A_1 + c_2 A_2, B]\} = c_1 \{[A_1, B]\} + c_2 \{[A_2, B]\}$, skew-symmetric: $\{[A, B]\} = -\{[B, A]\}$, satisfy the Jacobi identity and the Leibniz rule. They generate thus the Lie algebra with derivation referred by Heisenberg and Weyl. The wave models (of reduced wavelength $\tilde{\lambda} = \lambda/2\pi$, or $\hbar = h/2\pi$ in quantum mechanics) further require the Hilbert space $\mathcal{L}^2(\mathbb{R}^D)$ of Lebesgue square-integrable 'wave'-functions, where the operators $\hat{Q}_i$ and $\hat{P}_j$ are essentially self-adjoint.

The 4×4 matrix of Lie brackets (1)–(2) with the $2D$ column vector $\mathbf{W} := \begin{pmatrix} \mathbf{Q} \\ \mathbf{P} \end{pmatrix}$ and its transpose $\mathbf{W}^T$, written as

$$\{[\mathbf{W}^T, \mathbf{W}]\} := \left\{ \left[\begin{pmatrix} \mathbf{Q} & \mathbf{P} \end{pmatrix}, \begin{pmatrix} \mathbf{Q} \\ \mathbf{P} \end{pmatrix} \right] \right\} := \begin{pmatrix} \{[Q_i, Q_j]\} & \{[P_i, Q_j]\} \\ \{[Q_i, P_j]\} & \{[P_i, P_j]\} \end{pmatrix} = \begin{pmatrix} 0 & -\delta_{ij} \\ \delta_{ij} & 0 \end{pmatrix} \quad (3)$$

requires that, under linear transformation by a $2D \times 2D$ matrix $\mathbf{M} = \begin{pmatrix} \mathbf{A} & \mathbf{B} \\ \mathbf{C} & \mathbf{D} \end{pmatrix}$ with four $D \times D$ blocks, which maps $\mathbf{W} \mapsto \mathbf{MW}$, should continue to satisfy

$$\{[\mathbf{W}^T, \mathbf{W}]\} = \{[(\mathbf{MW})^T, \mathbf{MW}]\} = \mathbf{M} \mathbf{\Omega} \mathbf{M}^T = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} =: \mathbf{\Omega} \quad (4)$$

In 2×2 block form,

$$\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} -\mathbf{AB}^T + \mathbf{BA}^T - \mathbf{AD}^T + \mathbf{BC}^T \\ -\mathbf{CB}^T + \mathbf{DA}^T - \mathbf{CD}^T + \mathbf{DC}^T \end{pmatrix} \quad (5)$$

this entails the $D(2D - 1)$ *symplectic conditions*:

$$\mathbf{AB}^T, \mathbf{CD}^T \text{ are symmetric (and also } \mathbf{A}^T \mathbf{C}, \mathbf{B}^T \mathbf{D}), \quad \mathbf{AD}^T - \mathbf{BC}^T = 1 \quad (6)$$

$$\Rightarrow \mathbf{M}^{-1} = \mathbf{\Omega} \mathbf{M}^T \mathbf{\Omega}^{-1} = \begin{pmatrix} \mathbf{D}^T & -\mathbf{B}^T \\ -\mathbf{C}^T & \mathbf{A}^T \end{pmatrix} \quad (7)$$

Matrices that satisfy (6) are called *symplectic* and provide a minimal matrix representation of linear canonical transformations. The product of two such matrices is also symplectic, and so is the unit $\mathbf{1}$ and the inverse (7). They are thus a $D(2D + 1)$ -dimensional manifold that forms a *group*, denoted $\text{SP}(2D, \mathbb{R})$, where $\mathbf{\Omega}$ is called the symplectic metric matrix.

Geometric Canonical Transforms

In plane paraxial optics (with line $D=1$ screens), canonical transformations are represented by the 3-parameter manifold of 2×2 matrices of unit determinant $\text{Sp}(2, \mathbb{R})$ acting on $\begin{pmatrix} q \\ p \end{pmatrix}$. In the common setups with plane $D=2$ screens, the group of canonical transformations is the 10-parameter symplectic group $\text{Sp}(4, \mathbb{R})$ represented by 4×4 matrices acting on $(\mathbf{q}, \mathbf{p})^T = (q_x, q_y, p_x, p_y)^T$.

The correspondence between quadratic functions of the phase space coordinates, matrices and optical elements is established when the former are expressed in terms of the *Poisson operators* of differentiable functions $f(\mathbf{q}, \mathbf{p})$, given by

$$\{f, \circ\} := \sum_{i=1}^D \left(\frac{\partial f(\mathbf{q}, \mathbf{p})}{\partial q_i} \frac{\partial}{\partial p_i} - \frac{\partial f(\mathbf{q}, \mathbf{p})}{\partial p_i} \frac{\partial}{\partial q_i} \right) \quad (8)$$

acting on phase space functions with the Poisson bracket: $\{f, \circ\}g(\mathbf{q}, \mathbf{p}) = \{f, g\}(\mathbf{q}, \mathbf{p})$. When exponentiated with Taylor series in powers $\{f, \circ\}^n := \{\{f, \circ\}^{n-1}, \circ\}$, one finds in the $D=2$ group $\text{Sp}(4, \mathbb{R})$

3 anamorphic lens parameters:

$$\exp \left\{ - \sum_{i \leq j} c_{ij} q_i q_j, \circ \right\} \begin{pmatrix} \mathbf{q} \\ \mathbf{p} \end{pmatrix} = \begin{pmatrix} \mathbf{1} & \mathbf{0} \\ -\mathbf{c} & \mathbf{1} \end{pmatrix} \begin{pmatrix} \mathbf{q} \\ \mathbf{p} \end{pmatrix}, \quad \mathbf{c} = \begin{pmatrix} c_{x,x} & c_{x,y} \\ c_{x,y} & c_{y,y} \end{pmatrix} \quad (9)$$

3 anisotropic free space displacements:

$$\exp \left\{ - \sum_{i \leq j} b_{ij} p_i p_j, \circ \right\} \begin{pmatrix} \mathbf{q} \\ \mathbf{p} \end{pmatrix} = \begin{pmatrix} \mathbf{1} & \mathbf{b} \\ \mathbf{0} & \mathbf{1} \end{pmatrix} \begin{pmatrix} \mathbf{q} \\ \mathbf{p} \end{pmatrix}, \quad \mathbf{b} = \begin{pmatrix} b_{x,x} & b_{x,y} \\ b_{x,y} & b_{y,y} \end{pmatrix} \quad (10)$$

4 anisotropic magnifiers:

$$\exp \left\{ - \sum_{i,j} a_{ij} q_i p_j, \circ \right\} \begin{pmatrix} \mathbf{q} \\ \mathbf{p} \end{pmatrix} = \begin{pmatrix} e^a & \mathbf{0} \\ \mathbf{0} & e^{-a^T} \end{pmatrix} \begin{pmatrix} \mathbf{q} \\ \mathbf{p} \end{pmatrix}, \quad \mathbf{a} = \begin{pmatrix} a_{x,x} & a_{x,y} \\ a_{y,x} & a_{y,y} \end{pmatrix} \quad (11)$$

When applying matrices on phase space vectors to represent canonical transformations in an optical setup, one should remember that (if light goes from left to right) the leftmost optical element will correspond with the rightmost matrix factor (to act first), and successively in inverse order.

The group of $D=2$ canonical transformations $\text{Sp}(4, \mathbb{R})$ contains 4 *rotations* of phase space which close into the *Fourier group*, which is isomorphic to the unitary group of 2×2 (complex) matrices $\text{U}(2)_{\mathbb{F}}$. This contains x - and y - fractional Fourier transforms (FrFT), gyrations and screen rotations, which are also *generated* by exponentials of Poisson operators of quadratic functions of phase space given below. Writing for brevity $c := \cos \theta$ and $s := \sin \theta$, and identifying their generator functions, they are

$$\begin{array}{cccc} \text{isotropic FrFT} & \text{anisotropic FrFT} & \text{gyrations} & \text{rotations} \\ \begin{pmatrix} c & 0 & -s & 0 \\ 0 & c & 0 & -s \\ s & 0 & c & 0 \\ 0 & -s & 0 & c \end{pmatrix}; & \begin{pmatrix} c & 0 & -s & 0 \\ 0 & c & 0 & s \\ s & 0 & c & 0 \\ 0 & -s & 0 & c \end{pmatrix}, & \begin{pmatrix} c & 0 & 0 & -s \\ 0 & c & -s & 0 \\ 0 & s & c & 0 \\ s & 0 & 0 & c \end{pmatrix}, & \begin{pmatrix} c & -s & 0 & 0 \\ s & c & 0 & 0 \\ 0 & 0 & c & -s \\ 0 & 0 & s & c \end{pmatrix} \\ \frac{1}{2}(p_x^2 + p_y^2 + q_x^2 + q_y^2) & \frac{1}{2}(p_x^2 - p_y^2 + q_x^2 - q_y^2) & p_x p_y + q_x q_y & q_x p_y - q_y p_x \end{array} \quad (12)$$

These matrices are both symplectic and *orthogonal* (called ortho-symplectic); the isotropic FrFT commutes with the other three and is generated by the isotropic harmonic oscillator Hamiltonian. In general D dimensions, $\text{Sp}(2D, \mathbb{R})$ contains a $\text{U}(D)_{\mathbb{F}}$ subgroup of such phase space rotations represented by $2D \times 2D$ ortho-symplectic matrices.

Canonical Integral Transforms

The transformation between input and output wavefields due to the passage through an ideal paraxial optical setup are canonical transforms. Their kernel was found by Stuart A. Collins in optics and, independently, by Marcos Moshinsky and Christiane Quesne as a fundamental question in quantum mechanics, in 1970 and 1971.

Wave optics and quantum mechanics provide a Hilbert space of square-integrable wavefunctions $f(\mathbf{q})$ of $\mathbf{q} \in \mathbb{R}^D$ on which the phase space operators, satisfying (2) act as $\hat{Q}_i f(\mathbf{q}) = q_i f(\mathbf{q})$ and $\hat{P}_i f(\mathbf{q}) = -i \partial f(\mathbf{q}) / \partial q_i$ (for $\hbar = 1$ or $\hbar = 1$). Canonical transformations $\mathcal{C}_M$ characterized by generic symplectic matrices $\mathbf{M}$ will act on these operators through,

$$\mathcal{C}_M \begin{pmatrix} \hat{\mathbf{Q}} \\ \hat{\mathbf{P}} \end{pmatrix} \mathcal{C}_M^{-1} = \mathbf{M}^{-1} \begin{pmatrix} \hat{\mathbf{Q}} \\ \hat{\mathbf{P}} \end{pmatrix} = \begin{pmatrix} \mathbf{D}^T \hat{\mathbf{Q}} & -\mathbf{B}^T \hat{\mathbf{P}} \\ -\mathbf{C}^T \hat{\mathbf{Q}} & +\mathbf{A}^T \hat{\mathbf{P}} \end{pmatrix} \quad (13)$$

The *inverse* matrix (7) is required, as can be easily ascertained verifying that $\mathcal{C}_{M_1} \mathcal{C}_{M_2} = \sigma \mathcal{C}_{M_1 M_2}$, but for a sign σ that is not detectable in (13).

Regarding the action of $\mathcal{C}_M$ on wavefunctions, since the Fresnel transform of free flight is an integral transform, and so is the fractional Fourier transform, canonical transformations $\mathcal{C}_M$ will be *integral transform* operators that act as

$$f_M(\mathbf{q}) \equiv (\mathcal{C}_M f)(\mathbf{q}) := \int_{\mathbb{R}^D} d^D \mathbf{q}' C_M(\mathbf{q}, \mathbf{q}') f(\mathbf{q}') \quad (14)$$

where the integral kernel $C_M(\mathbf{q}, \mathbf{q}')$ is found applying $\mathcal{C}_M$ to $\hat{Q}_i f$ and $\hat{P}_i f$,

$$\mathcal{C}_M(\hat{Q}_i f) = (\mathcal{C}_M \hat{Q}_i \mathcal{C}_M^{-1}) \mathcal{C}_M f = \sum_{j=1}^D (D_{j,i} \hat{Q}_j - B_{j,i} \hat{P}_j) f_M \quad (15)$$

$$\mathcal{C}_M(\hat{P}_i f) = (\mathcal{C}_M \hat{P}_i \mathcal{C}_M^{-1}) \mathcal{C}_M f = \sum_{j=1}^D (-C_{j,i} \hat{Q}_j + A_{j,i} \hat{P}_j) f_M \quad (16)$$

Replacing the integral (14) on the left, $\hat{Q}_i$ and $\hat{P}_i$ will act on the $\mathbf{q}'$ argument of f , while on the right they act on the exterior argument $\mathbf{q}$ of the kernel $C_M(\mathbf{q}, \mathbf{q}')$. The operator $-i\partial/\partial q'_i$ in the left can be integrated by parts and applied on the $\mathbf{q}'$ argument of the kernel; this leads to 2D simultaneous differential equations:

$$q'_i C_M(\mathbf{q}, \mathbf{q}') = \sum_{j=1}^D \left(D_{j,i} q_i + i B_{j,i} \frac{\partial}{\partial q'_j} \right) C_M(\mathbf{q}, \mathbf{q}') \quad (17)$$

$$-i \frac{\partial}{\partial q'_i} C_M(\mathbf{q}, \mathbf{q}') = \sum_{j=1}^D \left(C_{j,i} q_i + i A_{j,i} \frac{\partial}{\partial q'_j} \right) C_M(\mathbf{q}, \mathbf{q}') \quad (18)$$

Multiplying these vector equations by $\mathbf{B}^{-1}$ and proposing a quadratic exponential solution, with appropriate normalization one finds

$$C_M(\mathbf{q}, \mathbf{q}') = K_M \exp i \left(\frac{1}{2} \mathbf{q}^T \mathbf{B}^{-1} \mathbf{D} \mathbf{q} - \mathbf{q}^T \mathbf{B}^{-1} \mathbf{q}' + \frac{1}{2} \mathbf{q}'^T \mathbf{A} \mathbf{B}^{-1} \mathbf{q}' \right) \quad (19)$$

$$K_M := \frac{1}{\sqrt{(2\pi i)^D \det \mathbf{B}}} \equiv \frac{e^{-i\pi D/4} \exp i(-\frac{1}{2} \arg \det \mathbf{B})}{\sqrt{(2\pi)^D |\det \mathbf{B}|}} \quad (20)$$

where $\arg \det \mathbf{B} \in \{0, \pm\pi\}$. When $M_0 = \begin{pmatrix} \mathbf{A} & 0 \\ \mathbf{C} & \mathbf{A}^{-1} \end{pmatrix}$, the kernel collapses to a Dirac δ^D and the transformation is no longer integral, but *point-to-point*:

$$(\mathcal{C}_{M_0} f)(\mathbf{q}) = \frac{\exp i(\frac{1}{2} \mathbf{q}^T \mathbf{C} \mathbf{A}^{-1} \mathbf{q})}{\sqrt{\det \mathbf{A}}} f(\mathbf{A}^{-1} \mathbf{q}) \quad (21)$$

The normalization and phase are determined by the requirement that, at the unit transformation, $\lim_{M \rightarrow 1} C_M(\mathbf{q}, \mathbf{q}') = \delta^D(\mathbf{q} - \mathbf{q}')$. The canonical integral transforms are *unitary* in $\mathcal{L}^2(\mathbb{R}^D)$:

$$(f, \mathcal{C}_M g) = (\mathcal{C}_M^\dagger f, g) = (\mathcal{C}_M^{-1} f, g) = (\mathcal{C}_{M^{-1}} f, g) \quad (22)$$

because

$$C_M(\mathbf{q}', \mathbf{q})^* = C_{M^{-1}}(\mathbf{q}, \mathbf{q}') \quad (23)$$

As in the geometric case, integral canonical transforms are fully invertible and no information is lost between input and output images.

Because it is emblematic, we should write the $D=1$ case of (19)–(21) explicitly; it is

$$C_M(q, q') = \frac{1}{\sqrt{2\pi i B}} \exp \frac{i}{2B} (Dq^2 - 2qq' + Aq'^2) \quad (24)$$

where $1/\sqrt{2\pi i B} \equiv e^{-i\pi/4} \exp(-\frac{i}{2} \arg B) / \sqrt{2\pi |B|}$, and the lower-triangular case (21) follows directly.

Issues Pertaining Integral Transforms

Canonical integral transforms include the Fresnel and fractional Fourier transforms as particular one-parameter subgroups of translation and a phase space rotation (of a spin-like nature – see below). They also include the time evolution generated by all quadratic wave/quantum operators and allow for complex extensions of some transformation parameters, thereby adding coherent states to the functions subject to group theoretical treatment.

The Metaplectic Sign

The square root in (20) and (24) indicates a double valuation: indeed, when for symplectic $M_1 M_2 = M_3$ we check carefully the composition of the integral kernels we find that

$$\int_{\mathbb{R}^D} d^D \mathbf{q}' C_{M_1}(\mathbf{q}, \mathbf{q}') C_{M_2}(\mathbf{q}', \mathbf{q}'') = \sigma_{1,2,3} C_{M_3}(\mathbf{q}, \mathbf{q}'') \quad (25)$$

with the *metaplectic* sign $\sigma_{1,2,3} = \text{sign}(\det B_3 / \det B_1 B_2)$.

Although overall signs are not commonly detected in wavefields, this sign ‘ambiguity’ is real and mathematically unavoidable. It is due to the fact that the set of canonical *integral* transforms covers the geometric $\text{Sp}(2D, \mathbb{R})$ group *twice*. The issue reminds us of the double cover that the spin group affords over the group of space rotations. A handle on this matter is provided by the kernel of the 1D Fourier transform $\mathcal{F}$, namely $F(q, q') = e^{iqq'} / \sqrt{2\pi}$, versus the *canonical* Fourier transform kernel for $F = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix} = \Omega$, which is $C_F(q, q') = e^{i\pi/4} e^{iqq'} / \sqrt{2\pi}$. Thus $C_F = e^{i\pi/4} \mathcal{F}$ and, while $\mathcal{F}^4 = 1$, one has $C_F^4 = -1$, and only $C_F^8 = 1$. The manifold of the symplectic group has the topology of a one-sheeted hyperboloid, whose *waist* is the ‘circle’ subgroup of isotropic fractional Fourier transforms, which may be infinitely covered. The double cover is called the *metaplectic* group $\text{Mp}(2D, \mathbb{R})$, of which linear canonical transforms are a faithful representation.

Exponentials of Second-Order Differential Operators

There is an important connection between canonical integral transforms and exponentials of *second-order* differential operators which follows the generation of the geometric $\text{Sp}(2D, \mathbb{R})$ presentation in (9)–(11) and in (12), replacing q_i, p_j with $\hat{Q}_i, \hat{P}_j$, Poisson brackets with commutators, and $\exp(\circ)$ with $\exp(i\circ)$.

There follow properties of self-reproduction of certain functions under a subgroup of canonical transforms: for example, writing $C_M \equiv C(M)$, the Hermite-Gauss wavefunctions $\Psi_n(q) = e^{-q^2/2H_n(q)/\sqrt{2^n n!} \sqrt{\pi}}$ in a planar waveguide satisfy

$$\exp\left(it \frac{1}{2} (\hat{P}^2 + \hat{Q}^2)\right) \Psi_n(q) = C\left(\exp t \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}\right) \Psi_n(q) = \left(C \begin{pmatrix} \cos t & -\sin t \\ \sin t & \cos t \end{pmatrix} \Psi_n\right)(q) = e^{i(n+\frac{1}{2})t} \Psi_n(q) \quad (26)$$

Upon decomposing $\begin{pmatrix} a & b \\ c & d \end{pmatrix} = \begin{pmatrix} \alpha & 0 \\ \gamma & \alpha^{-1} \end{pmatrix} \begin{pmatrix} \cos t & -\sin t \\ \sin t & \cos t \end{pmatrix}$, and using (26) and (21), one can then find the general linear canonical transform of these Hermite-Gauss functions as

$$\left(C \begin{pmatrix} a & b \\ c & d \end{pmatrix} \Psi_n\right)(q) = \frac{\exp\left(-\frac{d-ic}{a+ib} \frac{q^2}{2}\right)}{\sqrt{2^n n! \sqrt{\pi} \left(\frac{a+ib}{a-ib}\right)^n}} \frac{H_n(q/\sqrt{a^2+b^2})}{\sqrt{a+ib}} \quad (27)$$

Similar manipulations can be performed with the eigenfunctions of all quadratic operators: the repulsive oscillator $\frac{1}{2}(\hat{P}^2 - \hat{Q}^2)$, free waves $\exp(ikq)/\sqrt{2\pi}$ of $\frac{1}{2}\hat{P}^2$, eigenfunctions $\sim q^{i\lambda-1/2}$ of the dilatation generator $\frac{1}{2}(\hat{Q}\hat{P} + \hat{P}\hat{Q})$, or $\delta(q-\lambda)$ of $\hat{Q}^2$. Finally, Airy eigenfunctions of the linear potential $\frac{1}{2}\hat{P}^2 + \hat{Q}$ can be brought into the picture with the addition of linear terms of $\hat{Q}$, $\hat{P}$, and $\hat{1}$ to generate the six-parameter *Weyl-symplectic* group $\text{WSp}(2, \mathbb{R})$.

Complex Extension of Canonical Transforms

The parameters of the symplectic groups can be extended into a *complex* domain, characterizing thus $\text{Sp}(2D, \mathbb{C})$. The integral kernel (19) remains valid as long as it is an oscillatory and/or *decreasing* Gaussian in $\mathbf{q}' \in \mathbb{R}^D$. This condition requires that the term $i \mathbf{q}'^T \mathbf{A} \mathbf{B}^{-1} \mathbf{q}'$ must have a zero or negative real part. In the 1D case of (24) this means that $\text{Im}(b/a) \leq 0$.

Out of a Dirac delta at c , $\delta_c(q) \equiv \delta(q-c)$, one can produce a Gaussian of width $\omega > 0$ through the complex canonical transform

$$G_\omega(q-c) := \left(C \begin{pmatrix} 1 & -i\omega \\ 0 & 1 \end{pmatrix} \delta_c\right)(q) = \frac{1}{\sqrt{2\pi\omega}} \exp\left(-\frac{1}{2\omega}(q-c)^2\right) \quad (28)$$

Thus $c \begin{pmatrix} 1 & -i\tau \\ 0 & 1 \end{pmatrix}$ is the complex canonical transform for *diffusion* in time $\tau \geq 0$. It is no longer unitary in $\mathcal{L}^2(\mathbb{R})$, but within certain conditions can be made unitary in Bargmann-type Hilbert spaces over the complex domain.

The evolution of Gaussian wavefunctions in a harmonic waveguide, under fractional Fourier transforms, or under a quantum harmonic oscillator potential in time τ , can be computed using matrix algebra,

$$G_\omega(q-c; \tau) = \left(C \begin{pmatrix} \cos \tau & -\sin \tau \\ \sin \tau & \cos \tau \end{pmatrix} C \begin{pmatrix} 1 & -i\omega \\ 0 & 1 \end{pmatrix} \delta_c\right)(q) = \left(C \begin{pmatrix} \cos \tau & -\sin \tau & -i\omega \cos \tau \\ \sin \tau & \cos \tau & -i\omega \sin \tau \end{pmatrix} \delta_c\right)(q) \quad (29)$$

Coherent states are also complex canonical transforms of a Dirac δ_c . These are $\Upsilon_c(q) := \exp(c\hat{A}^\dagger) \Psi_0(q)$, with the raising operator $\hat{A}^\dagger := \frac{1}{\sqrt{2}}(\hat{Q} - i\hat{P})$, the ground oscillator state $\Psi_0(q) = \pi^{-1/4} e^{-q^2/2}$, and of displaced center $c\sqrt{2}$,

$$\Upsilon_c(q) = \pi^{-1/4} e^{\frac{1}{2}c^2} \exp\left(-\frac{1}{2}(q-c\sqrt{2})^2\right) = (2\pi)^{1/4} \left(C \begin{pmatrix} 1/\sqrt{2} & -i/\sqrt{2} \\ -i/\sqrt{2} & 1/\sqrt{2} \end{pmatrix} \delta_c\right)(q) \quad (30)$$

This the *Bargmann* transform that also maps the Hermite-Gauss wavefunctions $\Psi_n(q)$ on power functions $\sim z^n$ of a variable z on the complex plane. The time evolution of $\mathcal{Y}_c(q)$ under a harmonic waveguide can be found as in (29), and results in the center $c(\tau) = ce^{i\tau}$ oscillating with position $\sqrt{2\text{Re } c(\tau)}$ and momentum $\sqrt{2\text{Im } c(\tau)}$, drawing out circles on phase space.

Radial Canonical Transforms

When an $\text{Sp}(2D, \mathbb{R})$ matrix has diagonal blocks $\begin{pmatrix} a1 & b1 \\ c1 & d1 \end{pmatrix}$, canonical transforms of functions with definite angular momentum are reduced to 1D *radial* canonical transforms that conserve the angular momenta. The 2D kernel can be separated in polar coordinates as

$$q_1 = r \cos \theta, \quad q_2 = r \sin \theta, \quad r \in \mathbb{R}^+ = [0, \infty), \quad \theta \in \mathbb{R} \bmod 2\pi, \quad (31)$$

resulting in the measure $d^2q = r dr d\theta$. The generator of rotations, $\hat{L} = \hat{Q}_1 \hat{P}_2 - \hat{Q}_2 \hat{P}_1 = -i\partial_\theta$ is invariant under all $c \begin{pmatrix} a1 & b1 \\ c1 & d1 \end{pmatrix}$'s due to (6) and so are its eigenspaces of functions $f(r)e^{im\theta}$, for all integers $m \in \mathbb{Z}$. When ϕ is the angle between $\mathbf{q} \cdot \mathbf{q}' = rr' \cos \phi$, in each of these spaces we can perform the integral over ϕ to obtain

$$e^{im\theta} C_M^{(m)}(r, r') := \int_{-\pi}^{\pi} d\phi C_M(\mathbf{q}, \mathbf{q}') e^{im(\theta - \phi)} \quad (32)$$

This provides kernel for the m -radial canonical transforms,

$$f_M^{(m)}(r) \equiv (C_M^{(m)} f)(r) = \int_{\mathbb{R}^+} r dr' C_M^{(m)}(r, r') f(r') \quad (33)$$

$$C_M^{(m)}(r, r') = e^{i\pi(m-1)/2} \frac{1}{b} \exp\left(\frac{i}{2b}(dr^2 + ar'^2)\right) J_m\left(\frac{rr'}{b}\right) \quad (34)$$

where $J_m(z)$ is the Bessel function of the first kind. These transforms are unitary in the Hilbert space $\mathcal{L}^2(\mathbb{R}^+)$, with the inner product

$$(f, g)_{\mathcal{L}^2(\mathbb{R}^+)} := \int_0^\infty r dr f(r)^* g(r) \quad (35)$$

Among the 1D quadratic generators, squared momentum now displays a 'centrifugal' term:

$$\hat{P}_{(m)}^2 = -\left(\frac{d^2}{dr^2} + \frac{1}{r} \frac{d}{dr} - \frac{m^2}{r^2}\right) \quad (36)$$

while $\frac{1}{2}(\hat{Q}_{(m)} \hat{P}_{(m)} + \hat{P}_{(m)} \hat{Q}_{(m)}) = r d/dr$ and $\hat{Q}_{(m)}^2 = r^2$. The eigenfunctions will thus be of the corresponding quantum potentials, such as Laguerre-Gauss functions for the harmonic waveguide Hamiltonian $\frac{1}{2}(\hat{P}_{(m)}^2 + \hat{Q}_{(m)}^2)$.

Of course, the set $C_M^{(m)}$ with $M \in \text{Sp}(2, \mathbb{R})$ also represents that group, and belongs to *Bargmann's discrete* representation series D_+^k for $k = \frac{1}{2}(m+1)$. The well-known *oscillator* representation of $\text{Sp}(2, \mathbb{R})$ that occupied the previous two sections belongs to $D_+^{1/4} \oplus D_+^{3/4}$ for even and odd states on $\mathbb{R}$. There, $m = \mp \frac{1}{2}$ corresponds to kernels with $J\left\{\mp \frac{1}{2}(z) = \sqrt{2/\pi z} \begin{cases} \cos z \\ \sin z \end{cases}\right.$ on $\mathbb{R}^+$, which on the full real line reconstitute the oscillator representation that is double valued because it corresponds to half-integer m . For integer m the representations are single-valued so the composition sign σ in (25) is unity.

Phase-Space Representations of Freeform Optical Systems

Introduction

Since the early days of optics the classical shape of an optical surface used to be spherical or at least rotational symmetric, mainly because for this shape accurate manufacturing methods have been available. Accordingly the majority of optical systems was, and still is, rotational symmetric. Based on that symmetry assumption the well-known aberration theories, such as Seidel aberration theory (Gross, 2005), or Aldis calculus (Cox, 1964; Brewer, 1976) have mathematically been developed and intensely used for system analysis. However modern manufacturing methods, such as high precision diamond turning or 3D-printing, today allow for the accurate generation of optical surfaces which are free of any symmetry. Such surfaces are attractive to the optical designer, since they offer additional degrees of freedom to correct for astigmatic or other aberrations in complex folded systems (Thompson and Rolland, 2012). However, as freeform systems per definition do not allow any assumptions on symmetry, the well-developed aberration theories cannot be applied and more sophisticated analysis, such as nodal aberration theory (Fuerschbach *et al.*, 2014), is required. However these approaches are quite complex and require in-depth mathematical analysis of the system. Therefore it is desirable to find alternate simple methods to calculate and visualize aberration contributions within freeform systems, in order to allow the designer to analyze the optical system in a similar simple way as for rotational symmetric systems.

In this article we will apply the method of phase space in optics (Testorf *et al.*, 2010; Torre, 2005) for this purpose. The method allows an alternate access to the analysis of optical systems by employing an illustration of positions and angles of limiting rays. This has proven to be especially helpful for paraxial system analysis, but as we will see also aberrations can be very intuitively discussed in this context. Since symmetry assumptions are not required, this method proves to be a general tool to analyze and visualize freeform systems.

Within this article we will first introduce the general principles of phase space in geometrical optics. In a next step we will employ the method to visualize aberrations in symmetric and non-symmetric systems for the simplified two-dimensional case. Extending the analysis to all dimensions is however possible and finally allows an exact mathematical treatment and extraction of individual aberration contributions.

The Concept of Phase Space in Geometrical Optics

The concept of phase space in geometrical optics is based on an illustration of ray angles versus ray positions. This is most easily explained if we for the moment only consider meridional rays in the xz -plane of an optical system, as illustrated in Fig. 1. Any meridional ray at a given z -position is completely defined by two quantities, namely the distance to the optical axis x and the angle θ to the optical axis. If we furthermore weight the ray direction with the refractive index n of the propagation medium, we can define

$$u = n \cdot \tan \theta \quad (1)$$

Thus the vector $\mathbf{r} = (x, u)^T$ completely defines the ray-tracing behavior of any ray in an optical system. The vector components (x, u) of the ray can be illustrated as one point in a xu -diagram, which is called the phase space diagram. Propagation of the ray in an optical system in consequence corresponds to trajectories, respectively transformations in phase space. In Fig. 1 the relationship between standard ray propagation versus the corresponding trajectory in phase space is illustrated.

In the paraxial regime the ray-propagation and the corresponding trajectory in phase space is closely related to the so-called ABCD matrix-optics, respectively linear optical systems theory (Kloos, 2007). In this approximation the real optical system can mathematically be replaced by a sequence of linear transformations. This is illustrated in Fig. 2 where a sequence of reference surfaces D_i and D'_i , located at the vertex of the refractive surface, is introduced. The paraxial ray propagation then corresponds to

Fig. 1 Relationship between ray-propagation (left) and phase space trajectory (right) in an optical system. Reproduced from Rausch, D., Herkommer, A. 2012. Phase space approach to the use of integrator rods and optical arrays in illumination systems. Advanced Optical Technologies. Available at: <https://doi.org/10.1515/aot-2011-0002>.

Fig. 2 Real geometry (top) and paraxial representation (bottom) of a refractive lens system. The dashed line represents the paraxial ray-tracing, the solid line real ray-tracing.

the application of propagation steps T_i in between the surfaces D_i and D_{i+1} , and paraxial refraction S_i from D_i to D'_i at the spherical surfaces. If we denote the paraxial ray vector by $\mathbf{p}$, the matrix-optics rules define the following set of linear transformations as the ray propagates:

$$\mathbf{p}_{i+1} = T_i \cdot \mathbf{p}_i \text{ where } T_i = \begin{pmatrix} 1 & d/n \\ 0 & 1 \end{pmatrix} \quad (2)$$

$$\mathbf{p}'_i = S_i \cdot \mathbf{p}_i \text{ where } S_i = \begin{pmatrix} 1 & 0 \\ -\phi & 1 \end{pmatrix} \quad (3)$$

Here d denotes the distance between surfaces along the optic axis and ϕ is the optical power of the surface. Thus any paraxial ray, corresponding to an input ray $\mathbf{r}_0$ can paraxial be traced to surface D_i by application of a sequence of linear operations. Mathematically this is:

$$\mathbf{p}_i = \underbrace{T_{i,i-1} * S_{i-1} \cdots S_1 * T_{1,0}}_{M_{i,0}} * \mathbf{r}_0 \quad (4)$$

We can now translate the paraxial ray-tracing behavior into transformations within phase space. A visualization of appropriate reference rays in phase space, for example, the marginal ray and the chief ray, reveals the basic transformation properties and parameters of an optical system. This is illustrated in **Fig. 3** for a 2f-lens system, representing the propagation from the front focal plane to the back focal plane of a single lens. According to Eq. (2) the linear matrix T for free propagation corresponds to a shear into the x -direction, whereas a paraxial lens S , Eq. (2), corresponds to a shear in the angular u -direction. Thus the total propagation from the front focal plane to the back focal plane corresponds to a 90° rotation in phase space, which is expected since the 2f lens system translates angles into position and vice versa. It is also worth to note that area in phase space has an important interpretation. If the chief ray $(\bar{x}, \bar{u})$ and the marginal ray (x, u) of an optical system are employed as reference points, then the product $L = \bar{u} \cdot x - \bar{x} \cdot u$ is equivalent to the Lagrange invariant (Gross, 2005), which is a conserved quantity in conventional optical systems. In the phase space diagram this product corresponds to the shaded area, as illustrated in **Fig. 3**. In this sense we can generally state that area in phase space is conserved and paraxial propagation corresponds to a sequence of affine transformations to this area.

Visualization of Aberrations in Phase Space

Already analyzing the linear behavior in phase space reveals a lot of information about the system, especially the primary quantities like magnification or focal length (Kloos, 2007). However the paraxial equations do not contain any aberration effects, since each paraxial ray will behave in the same linear way and lead to the same transformation behavior. For aberration analysis it is therefore necessary to record and visualize the exact ray-tracing behavior and compare it to the above linear behavior. To do so,

Fig. 3 Illustration of chief and marginal reference rays in phase space and the paraxial transformation representing the system. The enclosed area corresponds to the Lagrange invariant.

Fig. 4 Illustration of real ray behavior in phase space, revealing nonlinear distortions corresponding to aberrations.

we can introduce a series of planar dummy surfaces D_i and D'_i at the vertex of each refractive surface, as illustrated in Fig. 2. In a sequential ray-tracer the surface D_i is placed directly before the real surface, and records the input ray, whereas the surface D'_i is arranged at the same position but sequentially arranged after the real surface and thus monitors the output ray. By performing raytracing the real ray intersection data $\mathbf{r}_i$ at each “input”-dummy surface D_i , and $\mathbf{r}'_i$ on the corresponding “output”-dummy surfaces D'_i can be recorded. Since the dummy surfaces are at the same position as the paraxial power of the linear system model, we can directly compare the paraxial behavior and real raytracing behavior. To illustrate this, a grid of rays, sampling the object (x) and aperture (u) space, is traced through the system and each ray is plotted in the phase space diagram. The result is presented in Fig. 4 and reveals the phase space transformation of the real system.

If we compare this result to the paraxial transformation as was shown in the previous Fig. 3 we notice, that non-linear deformations of the ray-pattern, respectively the phase space area, become apparent. At the image plane these deviations have a clear meaning and are illustrated in detail in Fig. 5. Since one ray fan at the image plane, corresponding to one column of the ray-grid, represents a set of rays that arrive at the same image point but under different angles, the lateral shift relative to the central ray simply corresponds to the transverse aberrations in x -direction. This is depicted in Fig. 5(b). In other words at the image plane we can define a general aberration vector, describing the difference between the linear ray $\mathbf{p}_I$ and the corresponding real ray $\mathbf{r}_I$

$$\Delta_I = \mathbf{r}_I - \mathbf{p}_I = \begin{pmatrix} \Delta x_I \\ \Delta u_I \end{pmatrix} \quad (5)$$

Obviously the spatial component Δx_I of this vector then represents the transverse aberration of this ray. The angular component can also be interpreted as the pupil aberration of the system. Following along these lines, we can define an aberration vector at any surface i within the system in the same way.

$$\Delta_i = \mathbf{r}_i - \mathbf{p}_i \quad (6)$$

Fig. 5 Difference in ray positions at the image corresponding to aberrations: (a) real ray grid at the image plane and linear behavior, (b) one ray fan corresponding to transverse aberrations (c) aberration vector in phase space, (d) color coded ray grid, where the color indicates the length of the aberration vector.

This vector represents the local deviation of the real ray from the linear ray in phase space and is shown in [Fig. 5\(c\)](#). The length of this aberration vector may thus be interpreted as a general measure of the current magnitude of the aberration of this ray. In consequence we can visualize the aberration of any ray in phase space by illustrating the length of the corresponding aberration vector $|\Delta|$, for example, as a color code. In [Fig. 5\(d\)](#) we show the color coded aberration field at the image.

It is worth to note, that since we have defined $u = n \tan \theta$ via [Eq. \(1\)](#), the free propagation between parallel reference surfaces D_i and D_{i+1} is of exactly the same linear form as the paraxial matrix in [Eq. \(2\)](#). Thus real raytracing in between parallel dummy surfaces exactly corresponds to the paraxial raytracing transformation.

$$\mathbf{r}_{i+1} = \mathbf{p}_{i+1} = \mathbf{T}_i \cdot \mathbf{r}_i \quad (7)$$

In other words free propagation does not introduce differences between paraxial and real ray propagation, i.e., aberrations. Therefore as expected the aberrations within the system are only due to the spherical surfaces and correspond to the difference between the real raytracing via the spherical interface according to Snell's law versus the linear behavior according to the paraxial refraction ([Herkommer, 2013](#)).

Visualizing Aberrations in Freeform Systems

The above described method is quite general, since all that is required to calculate the aberration vector of [Eq. \(6\)](#) are real ray-tracing data and linear ray-propagation data. In consequence this analysis can be transferred to more general optical systems, such as freeform systems ([Chen and Herkommer, 2016](#)). To illustrate this we use the following freeform prism from literature ([Takahashi, 1997](#)), which is often employed as a test and reference system for freeform designs. The design is illustrated in [Fig. 6\(a\)](#) and the detailed design data are listed in [Table 1](#). The illustrated prism geometry is, for example, employed in head-mounted displays to image a display into the pupil of the eye. Note that the design is usually obtained backwards, so in [Fig. 6\(a\)](#) the eye-pupil corresponds to the entrance pupil of the prism and the display corresponds to the image.

To illustrate aberrations in this freeform system the paraxial and real ray propagation in phase space can be compared, just as before for the rotational symmetric case. Again we denote the real rays by $\mathbf{r}$ and the paraxial rays by $\mathbf{p}$. However in a freeform system moreover a reference ray, serving as the reference axis and origin of the coordinate system, has to be defined, as we propagate through the system. In the rotational symmetric case this was not required, since the rotation axis naturally and uniquely defines the optical axis, however in freeform systems the reference has to be fixed. Here we choose the center ray on the pupil starting with an angle of 0° as a reference axis, as illustrated in [Fig. 6\(b\)](#). This reference ray is traced through the freeform system, defining surface intersection points at each surface $S1$ to $S4$. At each intersection we again insert a pair of dummy surfaces D_i and D'_i similar to the rotational symmetric system. The position of both dummy surfaces is identical to the reference ray intersection point, however again the first dummy is mathematically before, whereas the second dummy is after the surface in a sequential ray-tracer. Moreover all dummy surfaces have to be tilted to be exactly orthogonal to the reference ray in order to properly define the ray angles relative to the reference ray. This is illustrated in [Fig. 6\(b\)](#) for the example of surface 2 only. The positions of all dummy surfaces are listed in [Table 1](#). Note that positioning of these dummy surfaces can be performed in any ray-tracer after recording the global ray-tracing data and intersections of the reference ray.

Fig. 6 Illustration of a patented freeform prism (a) and corresponding location of auxiliary reference planes (b), leading to an unfolded auxiliary system of a sequence of dummy surfaces (c).

What should be mentioned is that the tilt and decenter of the surfaces in [Table 1](#) are all in global coordinates and referred to the entrance pupil (surface 0). The horizontal and the vertical field angle of this lens as we analyze here is $\pm 15^\circ$ in each dimension. Besides, the pupil diameter is 4 mm. The surfaces 1, 2 and 3 are anamorphic freeform surfaces, where K_x and K_y represent the conic constant, AR and BR describe the 4th and 6th order symmetric coefficients, AP and BP illustrate the 4th and 6th order asymmetric coefficients, Y and Z correspond to the decenter of the surface in Y and Z direction, and α shows the surface tilt.

After the above design preparations we can perform raytracing and record the real raytracing data r_i on each “input”-dummy surface D_i , and r'_i on the corresponding “output”-dummy surfaces D'_i with the help of any ray-tracer. Just in the same way as we did in the rotational symmetric case, we can thus define an unfolded auxiliary system of sequential dummy surfaces to record the ray patterns in phase space, as illustrated in [Fig. 6\(c\)](#). In order to compare the real rays to the paraxial rays we additionally have to determine the linear transformation matrices S_i and T_i . For the propagation matrices T_i all that is required are the distances d_i between consecutive parallel dummy surfaces D'_i and D_{i+1} . These data are available from any ray-tracer. Determination of the linear transformation S_i of the tilted and decentered real surfaces is more challenging and several methods can be implemented: The real ray grid data at the dummy surfaces D_i and D'_i can be used to determine the best fit linear transformation (S_i) from a sufficiently large set of rays and the corresponding set of equations ([Chen and Herkommer, 2016](#)). Alternatively we can use the predefined ABCD-function for tilted and decentered systems in [Synopsis CodeV10.8](#) to calculate the paraxial transformation matrix S_i . Both methods are appropriate to visualize aberrations fields, since the average linear transformation can be subtracted, however the later method will be used later in this paper for exact surface aberration calculations. In [Fig. 7](#) we illustrate the phase space behavior of the freeform prism. The color scale corresponds to difference between the real ray and the corresponding best fit linear ray and represents the length of the aberration vector $|\Delta|$, as defined in [Eq. \(6\)](#). [Fig. 7](#) thus illustrates the aberration field, which is built up as the rays propagate through the freeform system. The figure nicely illustrates the nodes of the aberration field, i.e., the areas where the aberration vector is small, moreover the missing symmetry leads to non-symmetric distributions.

Extension to 4d Phase Space

To explain the principles and allow visualization the above description was limited to the 2d phase space, since we only considered rays in the xz -plane. However this allows describing meridional rays within an optical system only. Already for rotational symmetric systems with finite field we are missing the saggital ray fans. Moreover in freeform systems rotational symmetry cannot be assumed. Therefore for the general case we have to consider a 4d phase space, which means that the position and direction of each ray in a certain reference plane has to be described by four quantities, namely $\mathbf{r} = (x, y, u, v)^T$. Here x, y are the

Table 1 Lens data of the freeform prism of reference including additional dummy surfaces

intersection points of the ray with the reference surfaces and u, v are the index-weighted direction tangents, which can easily be computed from the normalized direction vector (L, M, N) and the refractive index n by using

$$u = n \cdot \frac{L}{N}, \quad v = n \cdot \frac{M}{N} \quad (8)$$

In consequence the above employed matrix calculus needs to be extended to 4d, which however is straightforward. If we for example consider free ray-propagation between two consecutive parallel reference planes D'_i and D_{i+1} , as illustrated in Fig. 8, the corresponding exact ray-transfer matrix is quite similar to the 2d case.

$$\mathbf{r}_{i+1} = \mathbf{T}_i \cdot \mathbf{r}'_i \text{ where } \mathbf{T}_i = \begin{pmatrix} \mathbf{I} & d \cdot \mathbf{I} \\ 0 & \mathbf{I} \end{pmatrix} \text{ and } \mathbf{I} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \quad (9)$$

Thus only the introduction of the two-dimensional unit matrix $\mathbf{I}$ is required to extend the matrix $\mathbf{T}$ to the general case. Here it is again important to note, that since we employ the exact ray direction tangents in Eq. (8) and not any “paraxial” angles the above propagation matrix is exact, linear and identical to the paraxial transformation matrix also for larger angles. In other words again free propagation does not introduce any deviation between paraxial and exact ray-tracing.

Thus aberrations are only induced by the action of the real surface in between each dummy surface pair D_i and D'_i . The linear/paraxial transformation $\mathbf{S}_i$ of any 4d-ray input ray $\mathbf{r}_i$ into a paraxial output ray $\mathbf{p}'_i$ can be described by a linear matrix, which however now is 4-dimensional:

$$\mathbf{p}'_i = \mathbf{S}_i \cdot \mathbf{r}_i \text{ where } \mathbf{S}_i = \begin{pmatrix} A_{xx} & A_{xy} & B_{xx} & B_{xy} \\ A_{yx} & A_{yy} & B_{yx} & B_{yy} \\ C_{xx} & C_{xy} & D_{xx} & D_{xy} \\ C_{yx} & C_{yy} & D_{yx} & D_{yy} \end{pmatrix} \quad (10)$$

For the case of rotational symmetric lenses the matrix simplifies to a similar form as Eq. (9) and can be calculated from the surface power, in the same way as discussed in Eq. (2). In the general case we can determine the matrix either from a set of rays and

Fig. 7 Illustration of the phase space transformations corresponding to propagation through a freeform prism. The color code represents the normalized length of the aberration vector.

Fig. 8 Ray definition and propagation in between parallel reference planes. Reproduced from Chen, B., Herkommer, A.M., 2016. Generalized Aldis theorem for calculating aberration contributions in freeform systems. *Optics Express* 24 (23), 26999–27008.

then solving the equations to find the best-fit linear four-dimensional matrix. Another option is to employ the ABCD-function in Synopsis CodeV ([Synopsis CodeV10.8 News](#)), which is valid for decentered and tilted surfaces and defined for the general 4d-case. Application of this function in between D_i and D'_i will return the above 16-element linear transformation matrix. Note that in the general freeform case the sub-matrices A, B, C and D will not be symmetric, since especially a freeform surface will contain different curvatures in x and y direction and also prismatic structures.

If we, in comparison to the above linear analysis, now employ any ray-tracer to find the real surface intersection coordinates $\mathbf{r}_i$ at all of the reference surfaces we again can define, according to Eq. (6), an aberration vector Δ , which however is 4-dimensional. Therefore in summary the complete method as described in 2d is mathematically straightforward to be extended to the general case. However illustration of a 4d-vector and aberration field is challenging and in consequence visualization of the full information is difficult. Thus typically a reduction (projection) of the data will be required for visualization. For example the length of the aberration vector $|\Delta|$ can again be understood of as an aberration measure and illustrated as a color code, leading to similar pictures as shown in Fig. 7 in any 2d-visualization of the 4d-parameter field.

Even though visualization of the general situation is difficult, calculation is not. We will show below that the 4d-calculus is able to quantify aberrations and aberration contributions within freeform systems.

Calculation of Aberration Contributions at the Image

For rotational symmetric systems a long established theory of aberrations exists, and different classes of aberrations are defined, such as spherical, coma and astigmatism. The corresponding third order aberrations can be derived from paraxial raytracing only, and individual surface contributions can be calculated (Gross, 2005). Also an exact calculation of higher order surface contributions to lateral aberrations at the image exists: Within Aldis theory (Cox, 1964; Brewer, 1976) the aberration calculation is based on real ray tracing and paraxial (linear) ray-tracing of a given input ray. Application of this theorem allows exact calculation of the surface induced contribution to lateral aberrations at the image plane including all orders. Unfortunately for freeform systems this theorem can, due to the lack of symmetry, not be applied.

The phase space method described here does not require symmetry and is, same as Aldis theorem, based only on paraxial and exact rays. We will now mathematical prove that it can be applied to exactly quantify surface aberration contributions in freeform systems. To do this, the aberration generation and propagation in phase space has to be understood. Per definition the general aberration vector at a reference surface is a 4d-vector describing the deviation between the real ray coordinates and the paraxial ray coordinates. To better explain the relationships and propagation laws for aberrations let us switch back to the 2d-case for visualization. However the mathematical treatment is applicable to both, 2d and 4d cases.

In Fig. 9 the aberration generation and propagation is illustrated for the simple system of Fig. 2, where only two surfaces are involved. We will now mathematically and graphically follow the ray and aberration vectors through phase space.

During the analysis we will consider the aberration vector in front and after of each surface until we reach the image plane. We start with a general input ray r_0 at the object plane, as for example illustrated in Fig. 2. The free propagation to the first system surface D_1 is exact, via Eq. (7), and thus the real ray and the corresponding paraxial ray are equivalent:

$$r_1 = p_1 = T_0 \cdot r_0$$

Therefore the aberration vector in front of the real surface S_1 is zero, as

$$\Delta_1 = r_1 - p_1 = 0$$

As the ray passes the first surface (propagation from D_1 to D'_1) the ray picks up some aberration, since the input ray splits into a paraxial ray p'_1 (resulting from the linear surface matrix S_1) and the real ray r'_1 (refracted at the real surface), as illustrated in Fig. 9(a). Therefore we find the local aberration vector after surface S_1 to be:

$$\Delta'_1 = r'_1 - p'_1 = \underbrace{r'_1 - S_1 r_1}_{\delta_1}$$

Here and for later use we define the surface contribution δ_i to be the difference between the real traced ray r'_i and the paraxial traced ray $S_i r_i$ at surface i as:

$$\delta_i = r'_i - S_i r_i \quad (11)$$

After free propagation from surface S_1 to the front of surface S_2 we find the transformed, respectively sheared aberration vector, as illustrated in Fig. 9(b). In mathematical terms this corresponds to the application of the propagation matrix:

$$\Delta_2 = r_2 - p_2 = T_1 \delta_1$$

Fig. 9 Illustration of aberration propagation in phase space, where (a) to (b) represents the free propagation to surface S_2 , (b) to (c) illustrates the action of surface S_2 , and (c) to (d) resembles propagation to the image.

Similar as before the action of the subsequent surface S2 introduces some additional aberration contribution, which due to the above relations between the rays can be calculated as:

$$\Delta'_2 = \mathbf{r}'_2 - \mathbf{p}'_2 = \mathbf{r}'_2 - \mathbf{S}_2 \mathbf{p}_2 = \mathbf{r}'_2 - \mathbf{S}_2 \mathbf{T}_1 \mathbf{p}'_1 = \mathbf{r}'_2 - \mathbf{S}_2 \mathbf{T}_1 (\mathbf{r}'_1 - \delta_1) = \mathbf{S}_2 \mathbf{T}_1 \delta_1 + \underbrace{(\mathbf{r}'_2 - \mathbf{S}_2 \mathbf{r}'_1)}_{\delta_2}$$

The result can be interpreted in such a way that the surface S2 introduces an additional aberration term δ_2 which is added to the existing transformed (linear propagated) aberration vector of surface S1. In Fig. 9(c) we have again illustrated this graphically. Further propagation of the complete aberration vector to the front of surface S3 yields:

$$\Delta_3 = \mathbf{T}_2 \mathbf{S}_2 \mathbf{T}_1 \delta_1 + \mathbf{T}_2 \delta_2$$

In our graphical illustration of Fig. 9(d) this already corresponds to the image plane. At this point it has to be remembered that at the image plane the spatial component directly represents the lateral aberration of the particular ray. The equation above already suggests, that a recurrence relation can be established, since the aberration vector consists of terms corresponding to a sum of linear transformed aberrations δ_i from all proceeding surfaces. Indeed if we have n surfaces in the system we can continue this calculation to the image plane to find the following general result.

$$\Delta_I = \mathbf{r}_I - \mathbf{p}_I = \sum_{i=1}^n \mathbf{M}_{I,i} \delta_i = \sum_{i=1}^n \Delta_I^i \quad (12)$$

Here $\mathbf{M}_{I,i}$ represents the linear propagation matrix from the exiting dummy surface D'_i to the image plane I and is given by:

$$\mathbf{M}_{I,i} = \mathbf{T}_n \mathbf{S}_n \dots \mathbf{S}_{i+1} \mathbf{T}_i \quad (13)$$

Here the index n represents the last surface in the system, and $\mathbf{T}_n$ is the propagation from this last surface n to the image plane.

To summarize the above mathematical treatment: With Eq. (12) we have found a mathematical exact prove, that the total aberration of any ray at the image plane of an optical system consisting of n surfaces, can be expressed as the sum of individual surface contributions. Those individual surface contributions result from the differential rays at each surface i (i.e., the difference between linear and real ray tracing across surface i), which are linearly propagated to the image. In other words we have found a mathematical relation between surface aberration contributions and the exact ray aberrations at the image plane, including all

Fig. 10 Distortion analysis: In (a)–(d) the individual surface contributions are shown, where the red circles are the paraxial positions of the rays on image, and the blue cross represents the lateral distortion contribution of the surface, (e) illustrates the sum of the distortion contributions and is compared to the exact ray-tracing result at the image, (f) reveals the individual surface contributions for a single chief ray. Reproduced from Chen, B., Herkommer, A.M., 2016. Generalized Aldis theorem for calculating aberration contributions in freeform systems. *Optics Express* 24 (23), 26999–27008.

orders, quite similar to Aldis theory, however valid for freeform systems. The individual surface aberration contributions at the image plane, given in Eq. (12), are:

$$\Delta_I^i = M_{I,i} \delta_i = M_{I,i} (\mathbf{r}'_i - S_i \mathbf{r}_i) \quad (14)$$

This expression contains only real ray-tracing data before and after each surface and the linear System matrix $M_{I,i}$. Therefore this contribution vector can be obtained from the paraxial system representation and ray-tracing data only. No assumptions are made about symmetry or surface shape.

Aberration Contributions in a Freeform Prism

In order to demonstrate the application of the above mathematical treatment we apply it to the already introduced freeform prism. Following the above preconditioning, we have inserted dummy surfaces, as given in Table 1, and moreover determined all necessary transformation matrices S_i , T_i and $M_{I,i}$ by using CodeVs ABCD-linear system analysis (Synopsis CodeV10.8 News). Therefore calculation of the aberration contribution Δ_I^i of every ray at the image is now possible via Eq. (14), if in a prior real ray-tracing the ray-coordinates $\mathbf{r}_i$ and $\mathbf{r}'_i$ are recorded.

Fig. 11 Transverse aberrations for the (0°,0°) field, resolved for individual surface contributions. Reproduced from Chen, B., Herkommer, A.M., 2016. Generalized Aldis theorem for calculating aberration contributions in freeform systems. *Optics Express* 24 (23), 26999–27008.

As a first simple application the aberration contribution of a set of single rays can be studied. The chief-rays, representing different field angles, allow for a first useful application of the method. Since lateral aberrations of the chief-rays at the image plane correspond to the distortion of the system, we can simply apply our method to study distortion contributions in the freeform prism. To do so, we trace a set of chief-rays (i.e., rays starting at the center of the pupil) through the system. We use a set of 11×11 rays, scanning the field of view of $\pm 15^\circ$ in the x and y-direction. For every ray the ray-coordinates r_i and r'_i are recorded at all dummy surfaces. By applying Eq. (14) we can calculate the aberration contribution vector Δ_i^j on the image plane. The spatial (x,y) components of this aberration vector correspond to lateral distortion, i.e., the distortion, which is induced by each of the surfaces. This is illustrated in Fig. 10.

In Fig. 10(a)–(d), red circles represent the ideal positions of the rays on the image, calculated by the linear system matrixes, whereas the blue cross represents the ray aberration contributions of surfaces 1–4 on the image. Therefore the deviations of the blue cross from the red dots are the distortion contributions of each surface. The summation of all distortion contributions corresponds to the overall distortion at the image plane and are drawn as blue crosses in Fig. 10(e) and compared to the red circles directly obtained from real ray-tracing of the full system to the image in CodeV. As expected from Eq. (12) they exactly agree. The benefit of the phase space method is illustrated in Fig. 10(f), where the individual surface contributions are shown for a single ray of this grid. Obviously surface S2 and S3 are strongly contributing to distortion.

As a further example of the application of this method we can calculate and illustrate transverse ray-aberrations for a particular spot in the image plane. In Fig. 11 the meridional and saggital ray aberration contributions for each surface are illustrated for the central spot ($0^\circ, 0^\circ$) of the freeform system. The figure reveals that here surface S2 and surface S3 are strongly compensating each other. The sum of all surfaces, plus the paraxial contribution, perfectly coincides with the results achieved by exact tracing of these rays to the image surface, which again proves the validity of Eq. (12).

Conclusions

This paper presents a matrix based method to visualize aberrations via an analysis of phase space transformations. The difference between real and paraxial rays define a general measure which can be employed to illustrate the aberration generation and propagation in freeform systems.

Moreover mathematical exact aberration contributions in freeform systems could be derived. It was mathematical proven, that the exact ray aberrations at the image plane is identical to the sum of individual surface contributions. Those individual surface contributions can be calculated from a ray-tracing analysis of the system and paraxial propagation of the real and paraxial differential vector induced from an individual surface. All calculations can be performed with standard ray-tracing, provided additional dummy surfaces are installed in the system before. No assumptions about symmetry were required. In other words the method resembles a kind of Aldis theory for freeform systems, allowing the exact calculation of surface aberration contributions.

We have illustrated the method at the example of a freeform prism and shown that distortion and transverse ray-fans can be calculated and agree with the result of a standard ray-tracer.

This general work thus allows an “easy to implement” visualization and analysis of the aberration contributions within any freeform system. This will be beneficial in comparing freeform designs, performing tolerance analysis and improved optimization strategies.

Silicon Photonics; Ring Modulator Transmitters

Introduction

A silicon-based photonics integrated circuit (PIC) is a device that integrates multiple photonics components in a single planar structure. Silicon PICs lag behind compound semiconductor PICs in maturity. However the prospect of building large numbers of complex PICs for data communication applications at low cost by leveraging the CMOS industrial base has attracted much attention in academia and industry. One of the key components of a data communication PIC is a modulator. An integrated optical modulator is used to vary the properties of a light beam propagating in a PIC. Most commonly, modulators change the beam intensity but phase modulators are also used. An electro-optical modulator is used to translate an electrical signal into an optical signal that can be then transmitted and received through a photonic circuit. A ring optical modulator consist of a ring-shaped optical cavity that is optically coupled with a bus waveguide. Schematic top views of ring resonators are shown in Fig. 1. In a silicon PIC, the waveguides have a rectangular cross section with dimensions ranging between hundreds of nanometers to a few microns and the ring diameters for modulators are of the order of ten microns, whereas larger rings with diameters up to hundreds of microns can be used as filters.

Fig. 1(a) shows the waveguide arrangement for an “all pass” resonator while Fig. 1(b) shows the arrangement for an “add-drop filter” resonator. In the case of the “all pass” arrangement, all light incident in the device is passed through except for the resonant wavelengths that are absorbed or scattered in the resonator. In the “add-drop filter” configuration, resonant light is dropped through the “drop” port while non resonant light is transmitted to the “pass” port. The transfer function of both configurations from the input to the pass port is characterized by a Lorentzian notch centered at the cavity resonant frequency. Changing the effective index of the ring cavity shifts the resonant frequency and this mechanism can be used to modulate the amplitude of a laser in a wavelength-selective way. This is the main attraction of ring modulators: rings of different resonant wavelengths can be cascaded on a bus waveguide to modulate a number of different laser wavelengths. Similarly resonant “add-drop” filters can be used to de-multiplex a multi-wavelength signal at the receiver. In a silicon-based modulator, the change in the effective index can be achieved in a number of ways. Most commonly one uses plasma dispersion effects that link changes in the carrier concentration to changes in the real and imaginary parts of the index of refraction of silicon. Changes in the refractive index Δn as well as in the absorption coefficient $\Delta \alpha$ at a wavelength of 1.55 μm are given by (Soref and Bennet, 1987).

$$\Delta n = - \left[8.8 \times 10^{-22} \times \Delta n_e + 8.5 \times 10^{-18} \times (\Delta n_h)^{0.8} \right] \quad (1)$$

$$\Delta \alpha = 8.5 \times 10^{-18} \times \Delta n_e + 6.0 \times 10^{-18} \times \Delta n_h \quad (2)$$

where Δn_e and Δn_h indicate changes in the free-electron and free-hole carrier concentrations, respectively. The number of free electrons and free holes in the silicon can be changed using charge depletion, charge injection, or charge accumulation.

Various modulator schemes are shown in Fig. 2. A horizontal depletion modulator is shown in Fig. 2(a). The modulator consists of a light waveguide with a PN junction in the middle. By reverse-biasing the junction, one can expand the depletion region and therefore change the charge concentration. This modulation scheme is very fast and energy efficient but, because of the intrinsic doping of the light-carrying waveguide, it adds considerable optical losses to the device. It should also be noted that the maximum amount of index change is determined by the initial doping of the waveguide. A vertical depletion modulator (Fig. 2(b)) uses a similar modulation mechanism but the PN junction runs parallel to the plane of the circuit. This reduces the requirements for overlay control between the various doping steps. A current injection modulator consists of a PIN junction where the intrinsic region is the light carrying waveguide (Fig. 2(c)). This modulation scheme is relatively slow as it is limited by the majority carrier lifetime and has a relatively high power consumption due to the need to continuously

Fig. 1 Schematic top view of ring resonators in two configurations: (a) “all Pass” and (b) “add-drop filter”.

Fig. 2 Waveguide cross sections for various types of modulators: (a) horizontal depletion, (b) vertical depletion, (c) injection, and (d) accumulation.

replace carriers in the waveguide by injecting current in the junction. Balancing this disadvantages is the fact that large changes of the index are possible and the fact that the modulator can be built with low-loss intrinsic silicon. An accumulation modulator is shown in Fig. 2(d). The modulator consist of a waveguide with a MOS capacitor in the middle (running parallel to the plane of the PIC in this case). The capacitor can be charged and discharged through the p and n electrodes and the charge accumulating around the oxide barrier creates the index change. This scheme has the advantage of being fast and can in principle be built with relatively low intrinsic losses. It should be noted, however, that while it is possible to build a ring or a disk modulator based on this modulation mechanism, none has been demonstrated so far. There are other possible modulation schemes. One can change the index of the waveguide by changing the temperature of the silicon. This method is slow and it is not used for data encoding but given that it allows a large tuning range, it is usually used to tune ring resonance wavelengths to a desired value. Other methods use an electro-optical effect in the material that clads the silicon waveguide, for example there have been several demonstration of polymer-based ring modulators.

Fabrication

Photonic devices and circuits require an optical isolation layer and thus are based on a silicon-on-insulator (SOI) wafer. In order to create such a wafer, a layer of silicon with a thickness of a few hundred nanometers is placed atop a layer of silicon dioxide that is a few microns thick. Below this buried oxide is a bulk silicon substrate. The index contrast provided by the oxide layer below and air or a deposited oxide above enables optical confinement in the upper, thin, silicon layer in the vertical direction (Bruel, 1995).

The fabrication of ring-based modulators uses basic CMOS foundry process steps such as implantation of ions to form junctions, vias for ohmic contact, and a multi-layer back end of line. However, to enable lateral optical confinement, waveguides are formed by a partial etch of the silicon layer using plasma gas dry etch processes, a key step that enabled adoption of photonics into CMOS processes. In the most advanced foundries, 193 nm immersion lithography is used to define the optical structures in a resist, but lower resolution lithography has also been used successfully. For ring-based fabrication the critical dimension is the gap between the ring and the bus waveguide that can be as small as 100nm and requires tight control to avoid large dispersion in the optical properties. The lithographic pattern is then transferred into an oxide-based hard mask and finally into the SOI layer using a plasma etch. The optical propagation loss is a critical metric of performance for PICs and is highly dependent on the quality of the lithography and ensuing etch steps to ensure smooth, straight sidewalls. The depth of the partial etch (or alternatively, the height of the waveguide side wall) determines this loss value as it exposes more roughness to the optical signal. Therefore, this depth and its uniformity across a wafer is a tightly-controlled process parameter.

Often, there are two partial etches of the SOI wafer: one to define optical grating structures used for input/output of the optical signal onto the chip and the second for waveguides, often referred to as a shallow waveguide etch. The advantage of this shallow etch, which is usually 50% of the top silicon layer of the SOI wafer, is that it has low propagation loss on the order a few dB per centimeter for a straight waveguide. However, as mentioned, rings are formed by tight bends of the waveguide where the performance of shallow etched waveguides is very poor. This is primarily due to low optical confinement that causes the optical field to leak out of the waveguide through radiative modes. Bend losses can be alleviated by a deeper partial etch, resulting in a higher waveguide sidewall. Of course, this enhanced optical confinement comes at the expense of increased optical propagation loss. Therefore, these competing mechanisms present an optimization problem between process controls, etch depth and ring resonator bend radius in order to achieve optimized optical performance. A cross section of a partially etched waveguide is shown in Fig. 3 where important dimensions are denoted. A further complication of ring modulators that use a lateral junction is the resistance of the remaining portion of the un-etched SOI layer, referred to as the rib. A deeper etch results in better confinement which enables a tighter bend radius. However, increased optical loss and higher resistance of the rib layer present a design trade-off that must be properly accounted for to optimize device performance.

Optoelectronic Properties

As mentioned before, the transfer function of a ring resonator structure is a Lorentzian, characterized by its extinction ratio (ER) and full-width half-maximum (FWHM), a parameter which is often used to calculate the cavity quality factor (Q) by an inverse relation. A resonant cavity can be under, critically, or over-coupled which is easily determined by the trends of the ER and cavity Q. Following the treatment in [Bogaerts et al., \(2012\)](#), the transmitted optical spectrum for an all-pass configuration, as shown in [Fig. 1\(a\)](#) is given by the following equation:

$$T_n = \frac{I_{pass}}{I_{input}} = \frac{a^2 - 2ra \cos\phi + r^2}{1 - 2ar \cos\phi + (ra)^2} \quad (3)$$

where $a^2 = \exp(-\alpha L)$ is the internal loss mechanisms and comprises radiative losses due to surface roughness, bend loss, and free-carrier absorption from junction doping. These factors are largely process-dependent and can be considered static for a ring resonator design. However, careful consideration must be given to the coupler region design to ensure a proper balance between these three factors to achieve the desired coupling state. The coefficient r quantifies the coupling between the ring and the bus waveguide. Similarly, the transmitted optical power for the through and drop port for a ring resonator in the add/drop configuration shown in [Fig. 1\(b\)](#) is given by

$$T_p = \frac{I_{pass}}{I_{input}} = \frac{r_2^2 a^2 - 2r_1 r_2 a \cos\phi + r_1^2}{1 - 2r_1 r_2 a \cos\phi + (r_1 r_2 a)^2} \quad (4)$$

$$T_d = \frac{I_{drop}}{I_{input}} = \frac{(1 - r_1^2)(1 - r_2^2)a}{1 - 2r_1 r_2 a \cos\phi + (r_1 r_2 a)^2} \quad (5)$$

where r_1 and r_2 are the coupling coefficients between the ring and the add and drop waveguide, respectively. The state of coupling to the ring resonator is a relation between the input coupling, internal loss, and output coupling. Referring to the add/drop configuration in [Fig. 1\(b\)](#), the relationship

$$r_1 = r_2 a \quad (6)$$

defines the critical coupling condition. When $r_1 > r_2 a$ the cavity is under-coupled whereas when $r_1 < r_2 a$ the cavity is over-coupled.

In the critically-coupled regime the amount of light coupled to the cavity is equal to the amount coupled out and radiated due to losses. In this condition the extinction ratio (ER) and quality factor (Q), as can be seen from the spectra of the through and drop port plotted in [Fig. 4\(a\)](#), are very high. For SOI-based ring resonator cavities, a cavity Q in excess of 15,000 is routinely possible with greater than 15 dB ER. As the resonator cavity is moved into the under-coupled regime, the ER drops drastically as Q increases still, as can be seen from the plotted spectra in [Fig. 4\(b\)](#). An over-coupled resonator has both low ER and low Q. the spectra of which are plotted in [Fig. 4\(c\)](#). Therefore, ring resonator amplitude modulators that are critically coupled are desired as this

Fig. 5 Curved bus/ring resonator cavity coupler region.

maximizes the ER of the optical signal while keeping the cavity Q within a reasonable range. The cavity Q presents yet another design optimization as higher Q allows for denser channel spacing due to higher spectral isolation. However, higher Q means long photon lifetime within the optical cavity, increasing inter-symbol interference (ISI) as the modulation data rate increases.

There are many design types for coupler regions. In one example two parallel waveguides of a desired length are used to transfer power between the bus waveguide and ring cavity. This design allows for an analytical solutions for coupling strength using coupled mode theory (Marcuse, 2013). However, as is often desired for critical coupling, low input/output coupling ($\sim 5\%$ or less) are difficult to achieve due to the required short interaction length. Another design type of the coupler region is a co-curved bus/ring interaction region, shown in Fig. 5 where the bus waveguide follows the curve of the ring cavity with a constant gap separation.

This design offers a great degree of flexibility and allows for low coupling percentages between the bus and ring waveguides and is often preferred for processes where the minimum gap possible between two waveguides is large (on the order of 250 nm or greater). This design allows for shorter effective interaction lengths between the two waveguides as compared to the parallel waveguide design, it allows the resonant cavity to maintain a fully circular shape (which is often required for maintaining a constant loss and mode profile inside the cavity). However, it is more prone to fabrication variation in the gap between the ring/bus waveguide. The third design technique for the coupler region uses a straight bus waveguide and circular ring cavity as shown in Fig. 1, but with a narrower waveguide width for the coupler (W_{cp}) versus the ring cavity. In using a narrower waveguide width for the bus, the effective indices for the fundamental states of the two waveguides are increased, thereby enhancing the coupling between the two fundamental waveguide modes for a fixed effective interaction length. Another design factor for the add/drop configuration of the ring resonator cavity are the gaps between the ring cavity and the through and drop gap, referred to as G_{thru} and G_{drop} , respectively. For a fixed W_{cp} and ring width, one can control precisely the coupling percentage between the two waveguides by narrow variations in the gap between the two waveguides. This allows for accurate control of the input/output coupling to achieve critical coupling, as defined above.

A ring resonant cavity can be used as an amplitude modulator when its wavelength of resonance is modulated by electro-optic interactions. However, it is difficult, if not impossible, to control the absolute value of the resonance wavelength by fabrication techniques alone. The resonance wavelength can be controlled by changing the effective index of the material by using either the electro-optic effect or localized heating using integrated heaters. As mentioned, injecting carriers into the ring cavity causes a blue shift in the resonance wavelength and this is the main scheme for modulation. However, by maintaining a small DC bias on the diode, the resonance wavelength can be controlled with the same diode that is performing the modulation. This scheme is challenging to implement along with high-speed modulation in the driver design. By using a localized heater, the effective index of silicon can be finely tuned causing a red shift in the resonance wavelength.

The two main designs for an integrated heater are using the lowest metal layer directly above the ring cavity or with a resistive heater in the silicon rib material. To maximize the thermal profile overlap, the metal layer traces over the ring rib waveguide for most of the circumference of the ring cavity. This design is more robust to fabrication errors and burn-out from high current. However, due to the low resistivity of the typical metal layers available in CMOS-compatible processes, this design requires higher voltages as compared to other designs. Furthermore, due to CMOS back-end-of-line (BEOL) processes, the metal layer is several hundred microns away, further decreasing its thermal impact on the underlying silicon waveguide. Decreasing this length is not directly an advantage as interaction of the optical field with metal can lead to very high losses. These challenges can be somewhat mitigated by using highly resistive compounds like TiN instead of copper or aluminum, however, this material is not compatible with CMOS processes.

An integrated resistive heater in the silicon rib is created by forming a conductive channel in the otherwise intrinsic silicon material. Ohmic contacts are formed to this region by forming regions of high doping and conventional BEOL steps. By using an integrated resistor in the silicon rib, the local temperature within a few microns of the ring rib can be controlled, which in turn controls the material effective index, allowing for accurate resonance wavelength control. This design offers very efficient wavelength control and consumes power on the order of tens of microwatts per gigahertz in the wavelength range of interest. Careful consideration must be given to the resistor design in doping type and concentration of the current channel, its length and width to avoid leakage/fringing fields, and to optimize the resistance to achieve efficient wavelength control. A drawback of this design is the minimum proximity of the current channel to the waveguide due to foundry design rules. By using local temperature change, often near the coupling regions of the cavity and bus waveguides, a relatively small footprint of a few microns squared is required to efficiently control the wavelength of resonance, furthering the advantage of this heater design.

As mentioned previously, injection-type ring modulators use a P-i-N junction inside the waveguide to modulate the optical signal. The intrinsic bandwidth of this diode, however, is typically ~ 1 GHz. This is due to long lifetime of carriers in the intrinsic region. To overcome this bandwidth limit, equalization, or pre-emphasis, of the driving signal is required. The general principle of this approach is to decrease the amplitude of the lower frequency content of the driving signal, thereby boosting the amplitude of the high frequency content of the driving signal, relatively. The convolution of this driving signal frequency content and the intrinsic electrical frequency response of the diode results in increased bandwidth. This technique has achieved open eye diagrams up to 25 Gb/s using carrier-injection ring modulators with an intrinsic bandwidth of 1 GHz (Wu, *et al.*, 2016). As mentioned previously, there exists also an intrinsic bandwidth of the modulator from the photon lifetime due to cavity Q. So while pre-emphasis may boost the electrical bandwidth, the photon lifetime is a consequence of optical cavity design and is not affected by a pre-emphasized electrical signal.

In order to first understand the intrinsic electrical bandwidth of a ring modulator, an accurate circuit model is needed. The BEOL metal contribute small but known parasitic effects in the form of resistance and capacitance due to metal vias, substrate and metal layers, and are independent from the type of ring modulator, namely carrier depletion or injection. To develop a large signal model, the P-i-N junction may be modeled as a current source and a capacitor in parallel which are placed in series with a resistor, as shown in Fig. 6(a) from Wu *et al.* (2016). Similarly, a carrier-depletion ring modulator can be analyzed by the effective circuit shown in Fig. 6(b) from Rhim *et al.* (2015).

By performing S_{11} electrical measurements, the parasitics from these circuits can be derived through fitting. Subsequent DC current-voltage tests will further define the diode's current behavior. Note that the optical bandwidth due to the photon lifetime effect is also captured in the carrier-injection model. It is critical to note that the capacitor in this model, represented by C_{diff} is not a representation of the junction capacitance but that it is a mathematical consequence of the diode's small-signal behavior. Namely, it captures the transit time of the carriers across the junction and represents the change in current as a function of a bias change in time, which is the definition of capacitance. Therefore, C_{diff} must be carefully calculated using physical parameters and fitting models to accurately predict the time-dependent behavior of the modulator. Once the frequency response of the diode current is known, it can be mapped directly to a change in material index and thus modulation of the optical signal. This allows for an opto-electrical co-simulation to understand the high-speed modulation response of the modulator and allows for optimization of the pre-emphasized driving scheme often required to overcome the bandwidth limitations of a carrier-injection modulator.

The pre-emphasized signal can be generated by a few approaches and two will be briefly discussed here. By using a differential PRBS pattern, one can include a tunable delay and DC bias on the complementary output of the differential pair and combine the two outputs. This forms then the over/under-shoot components of the driving signal. The amount of delay relative to the data rate UI determines the frequency boost seen by the higher frequency components of the driving signal. Analogously, using a multi-tap FIR filter can produce a similar scheme. Often 2 or 3 taps are sufficient to produce the correct frequency response necessary for this driving mechanism. By using external hardware, one can accurately understand the required frequency response, making the design of a CMOS driver ASIC more direct. Once this frequency response is known, a tunable FIR filter integrated into the CMOS driver design can be easily implemented. Both approaches have been demonstrated (Li *et al.*, 2014) successfully to drive carrier-injection ring modulators.

Fig. 6 Equivalent circuit for a (a) carrier-injection and (b) carrier-depletion ring modulator.

Nonlinear Effects

Light that is tightly confined in a silicon photonic waveguide will experience optical nonlinearities. Whereas silicon is a centrosymmetric material and therefore does not exhibit any nonlinear effect of the lowest order ($\chi^{(2)}$) third-order ($\chi^{(3)}$) effects are going to be present. The resonant nature of the ring resonators further reduces the threshold power necessary to observe nonlinear effects. Some researchers have strived to demonstrate and exploit these effects for a range of applications including Raman amplification and lasing, self-phase modulation, all-optical processing, and even photon-pair generation. In the context of modulation, however, nonlinear effects are detrimental. In particular the most commonly observed nonlinear effect in ring resonators derives from thermal effects. Light absorption in the waveguide (either from two-photon absorption or from absorption by silicon defects) creates carriers that thermalize thus increasing the waveguide temperature. Because the index of refraction depends on temperature this effect will change the resonator resonant wavelength and therefore its transfer functions. The effect of this nonlinear behavior is shown in Fig. 7. As the power increases, the transfer function of the drop port of an “add-drop filter” changes (Fig. 7(a)). The system also shows a bi-stable behavior as evidenced by the difference in the transfer function measured in the same resonator by scanning the wavelength in the two directions. Initial modeling of this effects for high-speed depletion modulators has been published (Shin *et al.*, 2016).

Applications: Ring-Based DWDM Transceivers

The most important application of silicon microring modulators is in dense wavelength multiplexing (DWDM) transceivers. Because of their wavelength-selective nature microrings naturally lend themselves to DWDM applications. A schematic view of a DWDM transceiver is shown in Fig. 8. In this example a multi-wavelength laser source is injected in the transmitter circuit comprising a number of modulator rings each resonant with one wavelength of the incoming source. The modulators are used to encode a data stream on the individual laser lines. At the receiver side add-drop resonators are used de-multiplex the incoming data streams and direct them on individual detectors. Waveguides and possibly optical fibers connect the transmitter and the receiver. Transceivers like the one described here have been studied but no commercial implementation of this scheme is available at the time of writing. A key issue to warrant widespread deployment of ring-based DWDM transceivers is the implementation of

Fig. 7 Nonlinear bistability in ring resonators. (a) Change in the normalized transfer function of a drop port as a function of optical power. (b) Bistability, the transfer function changes depending on the direction of the wavelength sweep.

Fig. 8 Dense wavelength division multiplexing link. A multi-frequency source is injected in the transmitter and the various components are separately modulated. After transmission involving on-chip waveguides and off-chip fibers the modulated signals are coupled into a receiver chip where the various components are demultiplexed using drop filters and detected with on-chip photodiodes.

appropriate electronic circuits that drive the modulators, amplify and discriminate the received signal, and tune the rings to be in resonance with the appropriate laser line. Much work has gone into the design of special purpose circuits to achieve these goals. Most of these circuits have been designed in standard CMOS processes to take advantage of the large industrial base that supports these processes and given the relatively low analog bandwidth (10–20 GHz) required for these circuits.

Transmitter Circuits

Transmitter circuits differ considerably depending on the nature of the ring modulator. Depletion rings behave as capacitive loads and have bandwidths in excess of 20 GHz. For this reason relatively simple drivers comprising a chain of inverters and a final driver can be used. With such drivers bit rates in excess of 50 Gbps have been demonstrated. The bandwidths of injection rings on the other hand is severely limited by the carrier recombination time and typically are of the order of 1 GHz or less. For this reason injection-ring drivers require a significant amount of pre-emphasis and relatively large driving voltages. To achieve this pre-emphasis or finite impulse response filter stages need to be added to the driver circuitry. These additional circuits increase the complexity and power consumption of the drivers. With these caveats injection-ring modulator drives have been demonstrated for bit rates in excess of 20 Gbps.

Receiver Circuits

The receiver circuits for microring links do not present any peculiarity compared to standard photonic receivers. The main blocks of a receiver circuit include a trans-impedance amplifier, optional additional amplification stages, discrimination stages, and clock data recovery. The fact that the Silicon Photonic circuit can be closely integrated with the receiver circuit either through 3D integration or monolithic integration simplifies the design of the receiver first stage. The receiver sometimes is integrated with the control circuitry necessary to keep the drop filter in resonance with the incoming modulated laser.

Controllers

Controller circuitry is used to keep the transmitter modulator and drop-off filter in the receiver on resonance with the laser line. These circuits require a sensor and an actuator. For the sensing element a photodiode is often used to verify that the peak level of the modulated light is optimized. This can be accomplished using a peak detector in the receiver circuit. On the transmitter side a similar approach can be used if an add-drop configuration is used for the modulator ring. Two actuator strategies are commonly used with microrings. Increasing a ring temperature allows one to red-shift the resonant frequency. Charge injection allows one to blue-shift the resonance. Charge injection is more energy efficient than thermal tuning but the tuning range is limited. Ideally a combination of the two methods should be used in order to optimize power consumption.

Laser Sources

A multi-wavelength laser source is a key element of the DWDM link described earlier. Such source can be realized by combining multiple lasers through an AWG (array waveguide grating) or similar multiplexing component. Intrinsically multi-wavelength sources can also be used. Comb lasers based on quantum dot gain materials provide multiple independent low-noise lines that can be used for modulation. This solution is much simpler and less expensive than using multiplexed individual lasers.

Link-Level Considerations

Not much can be said about link-level tradeoffs here. In general a system-level analysis of the link is necessary to achieve optimal performance whereas optimizing a single component or figure of merit (such as the line toggle rate) will most likely result in sub-optimal link performance. It is also important to consider the compatibility and availability of different technologies in a single platform.

Optical Switches

Introduction

An optical switch is a networking element that directs light from optical input fiber(s) to optical output fiber(s) without converting the light to an electronic signal. An optical switch is controlled by an electronic controller. Applications for optical switches include DWDM network reconfiguration, test automation and packet networking.

Evolution From Static Links to Optical Switching

An optical fiber link carries information from a transmitter to a receiver. Early optical fiber network deployments comprised static optical links, of three general types. Wavelength add-drop networks are used for metro and long-haul deployments, and comprise wavelength add-drop rings and multi-wavelength point-to-point links. Passive optical networks (PON) have a root and leaf topology with time-division multiplexing and, in some cases, wavelength filtering. Intra-datacenter, LAN and super-computer deployments comprise single-point to single-point optical links. In all three environments, all of the optical paths were fixed when the equipment was installed. Switching of circuits, flows or packets happens in electronic elements positioned between an optical receiver and an optical transmitter, in an architecture known as optical-to-electrical-to-optical (OEO), Fig. 1. Even today this remains the conventional way to switch information. However, such OEO conversion uses transceivers at the switch, which are expensive, bulky, energy-intensive, and whose design usually supports a small set of bit-rates and protocols.

It is also possible to reconfigure or switch the optical links. This capability is known generically as optical switching. In optical switching, an electronic controller actuates a photonic element to change the connection of light between the optical transmitters and optical receivers. The architecture is known as optical-optical-optical (OOO), where the center “O” represents the optical switch itself. As will be described below, in some cases the photonic element is a switch that is positioned part-way along the optical path, and in other cases some aspect of the transmitter and/or receiver is actuated (e.g., the wavelength is tuned) which results in a change in the optical path.

An optical switch is transparent to signaling format and protocol (within limitations of spectral bandwidth, loss budget and other physical optical effects) and therefore simplifies the hardware requirements in the data plane. Because there is no electronic conversion of the signals, it is believed that this method of switching will consume less energy, an important requirement to maintain growth of data centers and super computers. Therefore, upgrades of bit-rate or protocol can be accommodated without the need to replace the switch.

Terminology of Optical Switching

The term used in this article is “optical switching”. The term “photonic switching” is also used for this capability, as it is the destination of the photons which is changed.

The term “all-optical switching” is sometimes used, but this term is ambiguous. For many years, in research labs, there have been elements where a control optical beam directly affects the destination of an optical signal, without the intervention of any transistors – this is truly an “all-optical” switch. It is out of scope for this article, as its practical use in communications systems is rare to date.

Fig. 1 A conceptual electrically switched optical-to-electrical-to-optical (OEO) network, compared to an optically switched optical-optical-optical (OOO) network.

Existing and Proposed Deployments of Optical Switches

Protection and provisioning

Optical switching is already widely deployed in metro and long-haul networks. The switching granularity is either a fiber, typically using 1×2 and 2×1 switches for protection switching when a fiber fails, or an individual wavelength, typically for adding new customers or adding additional bandwidth to a network, using reconfigurable optical add/drop (ROADM) and wavelength selective switch (WSS) technology. In current deployments of wavelength-granularity systems, the actual switching happens very rarely, although dynamic reconfiguration is frequently proposed as an important future opportunity. Switching time of milliseconds is typical within the switch itself, but the overall optical link takes 10's of seconds to several minutes to achieve stability in existing production networks.

Patch panels

Optical switching with fiber granularity is used in lawful intercept (fiber taps with selector switch), video production and test automation applications. Here, switches act as automated patch panels. Example technologies are: free-space MEMS to redirect beams from an input fiber collimator to a focusing lens of an output fiber, piezoelectric mechanical actuators to move a fiber relative to collimating and focusing lenses, and robot arms that move fiber patch cords. Switching time of milliseconds to seconds is typical.

Reconfiguration within data center

Optical switching with fiber granularity is currently being promoted for data center use where it can provide reconfiguration as workloads change, and can mitigate fiber wiring errors by craft people. Switching time of milliseconds is typical. However, there is a lack of published examples of real deployments.

Packet switch capacity growth

Optical switching with very fine granularity is a subject of much ongoing research, with the intent of capping or displacing OEO flow switches and packet switches, although there are currently no published commercial deployments. Switching time of nanoseconds to microseconds is typical. In this application, the energy-per-bit is a key metric, and photonic switching can in principle be more energy efficient than electrical switching. For clarity, optical switching applications are summarized in [Table 1](#).

Switch Characteristics

Granularity

The granularity of a switch is the smallest change that it can make. Example granularities of optical switches are fiber, wavelength, flow, and packet (ranked from coarsest granularity to finest granularity). As a rule of thumb, optical switches with coarser granularity are simpler to implement, easier to integrate with network operations, have better optical performance, are cheaper, and are more widely deployed than optical switches with finer granularity. Nonetheless, optics is penetrating further and further into electronic switches, and the opportunity for fine granularity optical switches is growing.

Scalability

The scalability of a switch is a conceptual term that indicates whether the technology and architecture of a switch can implement a large number of ports, without a catastrophic reduction in the quantitative parameters, compared to a switch with a small number of ports.

Quantitative Performance

Optical switches are commonly characterized by the following quantitative performance parameters.

Blocking probability is the fraction of legal connection maps that cannot be met because there is no available path inside the switch. Illegal connection maps are not included – for example, a map where two inputs are supposed to go to the same output is illegal, because this can never be serviced in a bufferless switch.

Table 1 Applications of optical switches

<i>Application</i>	<i>Switching time of the switch element itself</i>	<i>Commercial status</i>
DWDM network provisioning	Milliseconds to seconds	Widely deployed
Protection	Milliseconds	Deployed
Patch panel	Milliseconds to seconds	Deployed
Reconfiguration within data center	Microseconds to milliseconds	Emerging
Packet switch capacity growth	Nanoseconds	Development

Reconfigurability is related to blocking – it indicates whether or not existing connections have to be temporarily broken and reconnected when a new connection request arrives.

Switching time is the time between the switch receiving a request for a new connection, and the new lightpath is established and meets all the technical parameters.

Insertion loss (IL) is the fraction of optical signal power lost from the input to the output of the switch, typically expressed in dB.

Path dependent loss is the uniformity of insertion loss over different paths, typically expressed in dB. Optical receivers have finite dynamic range, and the noise penalty from optical amplifiers depends on the optical power level into the amplifier. Hence it is desirable if the path dependent loss is small.

Optical crosstalk is (in its simplest form) the ratio of the power at a specific output port from the desired input port, to the total power leaking from all the other inputs into that output port. A more realistic optical crosstalk calculation has a complicated dependence on the relative wavelengths of the input signals, coherence length and other link engineering parameters.

Multipath interference (MPI) is the fraction of optical power which takes a different path through the switch than the desired path. It arises from multiple back-reflections and leakages within the switch.

Extinction ratio (ER) is the ratio of the output power in the on-state to the output power in the off-state. Typical ER values are 40–50 dB for opto-mechanical switches, while the ER for photonic integrated circuit switches varies widely depending on the technology and architecture with reported values from 10 dB to 60 dB.

Polarization-dependent loss (PDL) is the range of insertion loss for different polarizations of the input light.

Differential group delay (DGD) is the range of time delay through the switch, for different polarizations of the input light. DGD causes deterioration of the optical signal quality, especially when large DGD is combined with large PDL as this is a non-linear effect that cannot be compensated using digital signal processing at the receiver.

Spectral flatness is the variation in the other technical parameters over the overall operating wavelength range of the switch, while ripple is the variation within the pass-band of a given channel. In the case of switches that are not wavelength selective (e.g., Mach-Zehnder switches, MEMS space switches), ripple and spectral flatness are equivalent terms. In the case of switches that are wavelength selective (e.g., WSS or ring-resonator switches), ripple indicates how much an individual optical signal will be corrupted, whereas spectral flatness indicates how the major parameters (insertion loss, PDL, DGD and so on) vary from one wavelength channel to another wavelength channel.

Engineering considerations of size, power consumption, cost, reliability and the ability to monitor the switch are also important parameters.

As a general rule, switches with small optical penalty are preferred, although to an extent the insertion loss and other penalties can be compensated using optical amplifiers and improved transmitters and receivers. The performance requirements vary greatly depending on what services are passing through the switch and the optical link budget from transmitters to receivers. Hence the quantitative requirements on an optical switch are specific to the network in which it is deployed.

Families of Optical Switch Technologies

Table 2 lists the families of optical switching technology that are most commonly used today. Key technologies are described in more detail later in this article.

Table 2 Optical switch technologies

<i>Family</i>	<i>Propagation medium</i>	<i>Mechanism</i>	<i>Types of actuator</i>
Free-space optical	Gas	Angle of the beam is steered by actuators	Tilting MEMS mirror Diffractive beam steerer comprising MEMS or liquid crystal Piezoelectric motor moves fiber relative to lens
Fiber-optic	Fiber	Fiber is physically moved by actuators	Mechanical motor moves fiber
Planar lightwave circuit	Optical waveguides on a chip	Actuators on the chip determine which waveguides the light passes through	Variable interferometer using thermo-optic, carrier injection, or electro-optic effects. Typical materials: silicon, silicon oxide/nitride, III-V semiconductor. Mach-Zehnder and microring interferometers are common. Variable gain in III-V semiconductor amplifier.
Tunable laser	Static network of DWDM filters	Actuator in the laser determines wavelength, which determines the route through the filters	Waveguide coupler, moved by MEMS. Thermo-optic, carrier injection, or movable mirror, in III-V semiconductor laser

Key Application Today: Reconfigurable Optical Add Drop Multiplexer, Using Wavelength Selective Switch

A reconfigurable optical add-drop multiplexer (ROADM) is an optical switch system with wavelength granularity, often used in access ring networks, and in rings and mesh networks that cover cities or larger regions. ROADMs can provide add/drop functions on rings, and cross-connection at hub locations. Initially, ROADMs were controlled by network provisioning software. Currently, many ROADM vendors offer the capability to integrate the ROADM controller into a software defined network.

At the heart of most ROADMs that are deployed today is one or more wavelength selective switch (WSS). A WSS has optical fiber inputs and outputs that each carries multiple wavelengths. The WSS selects which wavelengths from a given input go to a given output. Each output fiber can only carry one signal of a given wavelength. The WSS cannot change the color of the light. The WSS may also provide balancing of optical power across the wavelengths on an output fiber, and monitoring of optical power in each wavelength.

The fibers connected to a WSS are intended to carry multiple wavelengths, and thus network fibers connect directly to the WSS (typically via an optical amplifier to compensate for insertion loss and fiber loss). However, WSS are also used to connect from transceivers to/from the network fibers. A transceiver performs electro-optic conversion on only one wavelength at a time. Therefore between the WSS and optical transceivers there is an optical de/MUX, optical splitter/combiner, and/or an optical cross-connect to separate and direct the individual wavelengths. If the ROADM is used with coherent transceivers, then an external deMUX is not needed, because a coherent optical receiver contains a built-in wavelength filtering function achieved by its local oscillator laser. However, if the ROADM is used with direct detect transceivers, then an external deMUX is needed, because the receiver cannot distinguish light of different wavelengths.

Fig. 2 shows architectural differences between three types of ROADM: classic ROADM, colorless directionless (CD) ROADM, and colorless-directionless-contentionless (CDC) ROADM. The CDC ROADMs offer greater flexibility, but are more complex. For illustration purposes, the classic ROADM (which is colored, has direction, has contention) is shown with direct detect transceivers and therefore has external deMUX, whereas the CDC ROADM is shown with coherent transceivers and thus does not need an external deMUX.

ROADMs have the following attributes:

Degree

The degree is the number of network fiber pairs that connect to a ROADM.

Colorless

The ROADM is colorless if the wavelength that can be added at a given add fiber, or dropped at a given drop fiber, can be changed. Early ROADMs had a fixed wavelength at each add fiber and each drop fiber, and thus were “colored”.

Directionless

Each add fiber/drop fiber can connect to/from any network fiber port. If a given add fiber and drop fiber can only connect to a given network fiber, then the ROADM is not directionless.

Contentionless

In a contentionless ROADM, the ROADM can add and drop as many instances of a given wavelength as it has network fiber pairs. For example, consider a ROADM that has 3 network fiber pairs, as well as add and drop. Imagine that each fiber is carrying signals on the 1549.32 nm wavelength, as well as on other wavelengths. An operator may wish to add and drop all three of the 1549.32 nm signals. If the ROADM can achieve this, it is contentionless. In ROADMs that have contention, instances of the same wavelength would collide at some internal element, and hence cannot be simultaneously added/dropped.

WSS can be implemented using two types of wavelength plan:

Fixed Grid

The wavelengths are on a predetermined grid, typically 100 GHz or 50 GHz, and have a predetermined and static optical pass-band.

Flex-Grid

The separation of the wavelengths and the pass-band shape of each wavelength can be varied.

The most adaptable type of ROADM is a flex-grid CDC (colorless-directionless-contentionless).

Fig. 2 Types of ROADM (a) classic, (b) CD, and (c) CDC. The CDC ROADMs offer greater flexibility, but are more complex. For illustration purposes, the classic ROADM (colored, has direction, has contention) is shown with direct detect transceivers and therefore has external deMUX, whereas the CDC ROADM is shown with coherent transceivers and thus does not need an external deMUX. (After “CD ROADM – Fact and Fiction” Part 1: Applications, Fujitsu).

Fig. 3 Applications of optical packet switches: (a) Core router growth, (b) switch core growth, (c) high performance computing switched intraconnect.

Key Proposed Application: Optical Packet Switching

Optical packet switches are the subject of ongoing research, although they are not yet significantly deployed. For the sake of brevity, optical packet switches here include switches capable of switching individual packets, but also optical switches capable of switching custom-length frames or cells, or microsecond-duration dataflow.

Three applications are identified and shown in Fig. 3. Bandwidth requirements continue to increase in these applications. Electronic packet switches are ubiquitous today, but increasing their capacity faces increasing technical challenges related to heat dissipation, power consumption, and signal integrity.

Core Router Growth

At the core routers of a datacenter, an optical packet switch is added alongside an existing electrical router, to offload it. This may be particularly effective to offload longer packets and flows onto the optical packet switch, while leaving short packets in the electrical packet switch, because it is not practical to switch short packets optically.

Switch Core Growth

Conventional OEO switches contain OE and EO interfaces from/to other network elements, and these interfaces are connected through electrical switch chips and an electrical backplane inside the switch. Instead, the internal circuit can be replaced with additional EO and OE interfaces inside the switch, connected through an optical packet switch and an optical backplane.

HPC Switched Intraconnect

Dynamic connection between processing, memory, storage and I/O in a high performance computer (HPC).

In the first application, the optical packet switch switches light that has come from elsewhere in the network – for example, the optical transceivers may be on the other side of a datacenter from the optical packet switch. Hence the optical transceivers are also providing data transport. In the second and third applications, the additional optical transceivers are part of the switch, and are not providing data transport. The second and third applications become increasingly attractive when electrical chips have direct optical I/O, which has been proposed as a solution to the worsening I/O interconnect bottleneck of electronic chips.

Fast optical switch technologies have enormous data throughput, and can be highly efficient in terms of energy per bit. Their switch times are still relatively slow (several nanoseconds at best, for technologies that have good scalability), compared to electronic switches. Optical switches operate strictly as time-of-flight switches, and have no scalable capability for random-access-memory buffers. On the other hand, electrical packet switches switch at sub-nanosecond speed and most such switches today use a memory-based switching architecture, including random-access-memory buffering to handle contention. Hence a network using an optical packet switch cannot simply copy a conventional electronic packet network. Instead, the most practical solutions use a scheduler and ingress buffering to solve time-of-flight contention, and may also retain a conventional electrical switch for some classes of traffic (Fig. 4). Ingress buffering means that the source of the data is buffered at the network element before the optical

Fig. 4 Hybrid optical packet switch and electrical packet switch, illustrating ingress buffering for data that is handled by the optical packet switch.

packet switch, until the scheduler indicates that it is time to send. This architecture is illustrated in the figure. Thus, it is likely that electrical and optical packet switches will coexist and cooperate.

As will be discussed below in the section on planar lightwave technology, a realistic limit today for a fast photonic switch chip is around 32×32 to 64×64 ports. By a careful choice of parallel architecture, a switch implemented using these chips can implement 1000–4000 I/O ports, each having a throughput of 400 Gb/s or higher. Thus, the overall capacity of an optical packet switch can reach Petabits per second.

Free-Space Optical Switch Technologies

This section describes optical switches that operate by steering beams of light in air (or some other suitable gas). These switches are suitable for circuit switching as they switch relatively slowly (milliseconds), although some LCoS optical switches can achieve microsecond switching time and have been used for experiments with switching short-duration data flows. Generally, free-space optical switches have excellent optical performance. They are precision opto-mechanical assemblies, and so their manufacturing is relatively time-consuming. Careful engineering of vibration control and actuator feedback is used to achieve good alignment.

The 2D-MEMS, 3D-MEMS and piezoelectric optical switches described in this section have fiber switching granularity. If the application calls for switching individual wavelengths, then fiber-coupled wavelength deMUX and MUX components are needed before and after the optical switch. Single-mode and multi-mode versions have been built.

The WSS described in this section have wavelength switching granularity. They contain built-in diffraction gratings that perform wavelength deMUX and MUX. They always use single-mode fibers.

Liquid-Crystal on Silicon Wavelength-Selective Switch

Wavelength selective switches have a collimating lens after each input fiber, and collimate the incoming light onto a diffraction grating. The diffraction grating disperses each signal wavelength into a beam at a different angle. The beams then fall upon an actuator, which reflects them to a desired output fiber focusing lens. Generally, a diffraction grating is used to recombine signal wavelengths (which may be from different inputs) into the output fiber.

The form of the actuator has evolved over time. Early implementations used a MEMS-actuated mirror to tilt each beam, or used a small number of liquid crystal pixels to reflect the beam. By applying a controllable voltage to each liquid crystal pixel, its refractive index is changed. A set of liquid crystal pixels forms a phased-array reflector, which steers the reflected beam. These implementations are limited in their spectral resolution, and typically have fixed grid wavelength granularity at 50 GHz or more channel separation.

Liquid-crystal on silicon (LCoS) WSS were introduced commercially in the mid-2000s and are particularly intended for flexible grid operation. A concept demonstration of a WSS with LCoS optical sensor is shown in Fig. 5. The liquid crystal medium is directly on top of a silicon CMOS control chip. The size of the pixels in an LCoS is very small compared to the size of the beam. The number of liquid crystal pixels hit by the beam depends on the spectral width of the signal in the beam. The control system chooses the appropriate set of pixels depending on the present set of wavelength channels in each fiber, which is learned from network operating software. LCoS granularity down to 6 GHz channel separation is possible. Commercial LCoS WSS with up to 20 fibers are commonly available today.

3D Micro-Electro-Mechanical Optical Switch

3D-MEMS optical switches became well-known around the year 2000. They are currently deployed mostly in patch panel and reconfiguration applications.

Fig. 5 Wavelength selective switch using liquid crystal on silicon.

A 3D-MEMS, as schematically demonstrated in Fig. 6, has a collimating lens on each input fiber that produces a collimated beam in a gas. The beam reflects off a mirror in a first plane of mirrors, which sends the beam to a mirror in a second plane of mirrors that steers the beam into the acceptance angle of a focusing lens of an output fiber. The beam travels a distance of centimeters through the gas. Each mirror array is a silicon substrate, with tiltable micro-mirrors that are driven by MEMS actuators. A controller tilts each mirror by a variable amount to achieve the desired beam alignment. Typically, an optical monitor in the output fiber provides feedback to the controller.

Most 3D-MEMS optical switches have from 64 to a few hundred ports, and the largest built had more than 1000 ports. Insertion loss is typically less than 3 dB, return loss and crosstalk are low, and switching time is in the order of milliseconds to 10's of milliseconds. The optical switch is non-blocking, operates over a wide wavelength range, and may be bi-directional (depending on the control system). The controller requires careful engineering to achieve and maintain good alignment, and to compensate for environmental vibration.

For a 3D-MEMS optical switch with N inputs and N outputs, there are $2N$ mirrors. For example, a 300×300 switch needs 600 mirrors.

The figures illustrate the 3D-MEMS concept. In practice, the optical path may be folded using static mirrors, to reduce physical volume and to allow the input and output fibers to be assembled in the same plane.

2D Micro-Electro-Mechanical Optical Switch

2D-MEMS optical switches were fashionable in the late 1990s, attracting significant research and industry investment. However, in more recent years they have attracted less attention than 3D-MEMS.

In a 2D-MEMS device, as conceptually illustrated in Fig. 7, each optical input fiber has a lens which creates a collimated beam, and each output fiber has a focusing lens and is at 90° to the input. There is a 2D array of mirrors built on a silicon substrate by MEMS manufacturing processes. To connect an input to an output, one mirror is inserted into the beam, and the other mirrors are moved out of the way. The mirror has two very well defined states; it is either "not inserted" or is "inserted". Several insertion

Fig. 6 Schematic of a 3D-MEMS optical switch.

Fig. 7 Schematic of a 4×4 2D-MEMS optical switch.

Fig. 8 Schematic of a piezoelectric optical switch. Reproduced from Jencotech, Available at: <http://www.jencotech.com/documents/PolatisOverviewRev1.pdf>.

mechanisms have been used: the mirror is stood up/laid down, the mirror is slid sideways into the beam, or the mirror is lowered into the beam. Actuators are electrostatic or micro-motors. The mirror is typically silicon, with a reflective coating. Generally, the angle of the mirror is defined by the manufacturing and is not adjustable. For an optical switch with N inputs and N outputs, there are N^2 mirrors.

Switching time is typically in the order of sub-milliseconds, which is 5–10 times faster than the 3D-MEMS devices. The advantage is due to simple direct digital control operation of the mirror movement from a rest position to an active position.

A 2D-MEMS has excellent optical properties because the optical path contains just 2 lenses and one mirror. However, it becomes difficult to achieve good optical beam control at large port count, as the distance between the lenses is larger and thus angular alignment during manufacturing becomes more critical. Typical larger elements are around 16×16 ports.

Piezoelectric Moving-Fiber Optical Switch

A piezoelectric optical switch (Fig. 8) is used in similar applications as a 3D-MEMS switch. It has similar capabilities, performance, physical size, and number of ports as 3D-MEMS, but it uses a different optomechanical mechanism.

In a piezoelectric optical switch, each input fiber has a collimating lens, and each output fiber has a focusing lens and there is a gas region between the lenses in the middle, much like the 3D-MEMS. The position of each fiber is moved slightly with respect to its lens, using piezoelectric actuators, so that the beam from the collimating lens is steered toward a desired focusing lens, and the acceptance angle of the focusing lens is tilted so as to couple the beam into the output fiber.

Planar Lightwave Circuit Optical Switch Technologies

Planar lightwave circuit (PLC) optical switches comprise optical waveguides which are manufactured on wafers using lithographic processes, then diced into chips and packaged with optical fibers for optical I/O. Each connection from an input to an output on the chip is called a lightpath. To set up the lightpaths, electrical controllers connect to the planar lightwave circuit. The electrical controllers are usually off-chip. In almost all cases, PLC optical switches are single mode and therefore are compatible only with single mode fiber.

Materials and Physical Principles

A wide variety of materials have been used for PLC optical switches, including silicon-on-insulator, silicon dioxide, silicon oxynitride, GaAs, InP and related III-V semiconductors, polymers, electro-optic polymers, and electro-optic crystals of which lithium niobate and PLZT are the most popular.

PLC optical switches operate using one of the following physical principles:

Interferometer

The electrical signal creates a change in refractive index of the optical waveguide. Each optical switch cell is arranged as an interferometer with 2 inputs and 2 outputs. Changing the refractive index changes which input is connected to which output. The most common forms of interferometer are Mach-Zehnder and microring resonator. To change the refractive index, the electrical signal changes the temperature of the waveguide (thermo-optic effect in dielectric, semiconductor or polymer), changes the density of electrical carriers (carrier injection in semiconductors), or changes the electric field (in materials with an electro-optic coefficient).

Moving waveguide coupler

The electrical signal causes a waveguide to move physically. The moving waveguide is part of a directional coupler with 2 inputs and 2 outputs. Moving the waveguide changes which input is connected to which output. See the section on waveguide-MEMS.

Blocker

The electrical signal changes the optical waveguide from absorbing to having gain. The optical switch cell is a gate with 1 input and 1 output. The gate blocks or transmits light. See the section on SOA switches.

All these PLC optical switches are spectrally broadband and therefore switch all wavelengths within a 10's-nm wide spectrum, except the microring resonator which is narrowband and switches a single WDM wavelength.

Scaling up a Planar Lightwave Optical Switch From Small Building Blocks

Many planar lightwave optical switch technologies can only implement cells with 1 or 2 inputs and outputs. To achieve scalability, these cells are connected together in a switch matrix, preferably with as many cells as possible on one die. In addition to the external characteristics of the overall optical switch, the internal topology of the switch matrix can be described using the following characteristics:

Symmetric

In a symmetric topology, every lightpath uses the same number of cells. In an asymmetric topology, the number of cells in a lightpath depends on the lightpath.

Deterministic

In a deterministic topology, there is exactly one path from a given input to a given output. In a non-deterministic topology, there is more than one possible path, and a routing algorithm considers all the requested connections.

Stages

In a single stage switch, one cell is actuated per lightpath. In a multi-stage switch, multiple cells are actuated per lightpath.

Some important topologies are listed in the [Table 3](#) and illustrated in [Fig. 9](#). For simplicity, the table shows the case where the number of input ports N is equal to the number of output ports, which is known as an $N \times N$ switch. Multi-stage switches are most efficient when the number of ports is a power of 2. Any of these switch matrices can, in principle, be cascaded to make a Clos architecture, although currently actual deployments of a Clos optical switch are rare to nonexistent.

The **crossbar** fabric is a type of switching technology where each node is connected to every other node. The interconnection between the inputs and the outputs is achieved by appropriately setting the states of the 2×2 switches. For a $N \times N$ switch, the total number of 2×2 switching cells is N^2 . [Fig. 9\(a\)](#) demonstrates connectivity in a 4×4 switch matrix. To connect input i to output j , the light traverses the 2×2 switches in row i until it reaches the column j and then traverses the switches in column j until it reaches output. The shortest light path length is 1, and the longest is $2N - 1$, resulting in large variation in path length. The crossbar architecture is non-blocking, has a simple layout, and small cell count at small N . Drawback of this topology is the large number of crossings and large cell count at large N .

The **switch and select** architecture consists of an input switch array, an output switch array, and a passive crossover network. The example of [Fig. 9\(b\)](#) demonstrates a 4×4 switch matrix. The number of switches is uniform in all optical paths and follows logarithm scaling instead of the linear scaling. The passive crossover network connects the N^2 outputs from the input switch array to the N^2 inputs of the output switch array. The large cell count at large N and the large number of on-chip waveguide crossings limit the potential for scalability and introduces different insertion loss on the different paths.

Table 3 Switch topologies used with planar lightwave circuit switch cells

Topology	# Cells per path	# Cells total	Type	Blocking	Strength	Weakness
Crossbar	1 to $2N - 1$	N^2	Single stage, symmetric deterministic	None	Simple layout Small cell count at small N No blocking	Many crossings Large variation in path length Large cell count at large N
Switch & select	$2 \log_2 N$	$2N(N - 1)$	Multi-stage symmetric deterministic	None	One plane of crossings	Large cell count at large N
Path independent loss	$2 \log_2 N + 2$	$2N^2$	Multi-stage symmetric non-deterministic	None	Equal loss on all paths	Large cell count at large N
Banyan	$\log_2 N$	$(N \log_2 N)/2$	Multi-stage symmetric non-deterministic	Blocking	Small number of cells	High crosstalk Blocking
Benes	$2 \log_2 N - 1$	$N \log_2 N - N/2$	Multi-stage symmetric non-deterministic	Almost none	Small number of cells	Very high crosstalk
Dilated Benes	$2 \log_2 N + 2$	$2N(\log_2 N + 2)$	Multi-stage symmetric non-deterministic	Almost none	Low crosstalk Efficient routing algorithm	Larger number of cells in path

Fig. 9 Schematic of four topologies constructed from small switches: (a) crossbar switch, (b) switch and select switch, (c) path-independent loss (PILOSS) switch, and (d) dilated Benes switch.

PILOSS is another standard switch topology for building $N \times N$ switches. It consists of a matrix of 2×2 element switches as shown in Fig. 9(c). It usually is designed to have the element switches 'normally' OFF (cross-state), therefore reducing the total power consumption of the switch matrix. In this topology, light always passes through N element switches and $N - 1$ intersections, thus experiences the equal attenuation for all the $N^2 -$ ways of paths. The maximum number of ON state element is N , making the PILOSS topology energy-efficient. For this reason, it is believed to be one of the most promising towards larger N .

A hybrid dilated Benes with crosstalk suppression is shown in Fig. 9(d), comprised of an ingress column of 1×2 cells, two vertically replicated 4×4 Benes in the middle, and an egress column of 2×1 cells. By replacing the central column of 2×2 cells each with a 2×2 dilated Banyan, crosstalk noise can be suppressed. In addition to crosstalk suppression, use of wavelength constraint routing (routing of lightpaths within the switch matrix to minimize how many time different lightpaths meet within the switch matrix) reduces output crosstalk.

Materials for Planar Lightwave Optical Switches

Silica-on-silicon is a dielectric that is widely used in passive planar lightwave circuits. The core and cladding are composed of silicon dioxide with different dopants that modify the refractive index slightly. The fabrication process is inexpensive, connection to single-mode optical fiber is relatively easy and low loss, and optical propagation loss in the waveguide is low. Silica has a thermo-optic effect which can be used as a switch actuator. However, bends are very large, due to the small refractive index step between the core and cladding of the waveguide. Therefore it has very poor scalability for an optical switch.

Silicon oxynitride (SiON) is similar to silica-on-silicon, except that the waveguide is made of different compositions of SiON. The refractive index of the SiON can be adjusted in the range 1.45–2.01 depending on the composition, which is wider than the refractive index variation in silica. This allows smaller bend radius. SiON is increasingly used for passive planar lightwave circuits, but its use for optical switches is relatively uncommon.

Perovskite crystals include lithium niobate and lead lanthanum zirconium titanate (PLZT). Waveguides are formed by doping the material, typically by diffusing metal ions into the material. Perovskites are used for very fast switches with up to 8 ports. They have an electro-optic effect, whose switch time is limited only by the electronic controller. The electro-optic effect is much weaker per unit length than thermo-optic and carrier injection effects, so a perovskite optical switch cell is large. Therefore, perovskites do not scale up to very large port count.
